This work is funded by the *Consejo Nacional de Ciencia y Tecnología – CONACYT* (the Mexican National Council for Science and Technology).

I would like to thank Prof. Dr. Alberto García-Ortiz, my Ph.D. supervisor, for his invaluable help in this process. He knows how to raise students to the level of independent researchers. I would also like to thank Prof. Dr. X for his guidance and for his time to review this work. Moreover, I would like to thank the members of the graduation committee for their review and suggestions. I would like to thank Mexico and Conacyt for financially supporting my PhD. Thanks to Germany for being my second home during my preparation. Special thanks to Tovalin, Julian Rosales, Fernando De la Torre, Ulises Ponce, Carlos Cruz, and Kai Müller for their inspiration for teaching.

I would also like to thank my colleagues Ardalan Najafi, Amir Najafi, Wanli Yu, Yanqiu Huang, Robert Schmidt, Yizhi Chen, Jinming Sun, and Andreas Beering. They are excellent human beans, professional, supportive, and brilliant minds. I also want to thank David Rotermund and Klaus Pawelzik (Institute for Theoretical Physics, University of Bremen) for their collaboration and guidance. A special thanks to all the students I have supervised during my Ph.D. for teaching me so much. I would like to thank Kerstin Janssen and Peter Lutzen for their support in the research department. I thank the University of Bremen, ITEM, and the Studierendenwerk for being virtuous institutions. It would not be possible to reach this point without your kind existence.

I would like to thank Atena Berhang and her family for their sweet and constant support. Likewise, I want to thank my parents for their effort and encouragement to practice virtue and universal love. I want to thank my brothers Kevin and Efren, great sages, my best friends. I also thank all my family members and friends for their support and good wishes during my doctorate.

I would like to thank Marcus Aurelius, Epictetus, Seneca, and Nezahualcóyotl for their mentorship.

Abstract

The use of Artificial Intelligence (AI) is entering a new era based on the use of ubiquitous connected devices. The sustainability of this transformation requires the adoption of design techniques that reconcile accurate results with cost-effective system architectures. As such, improving the efficiency of AI hardware engines as well as Machine Learning (ML) portability must be considered.

In the emerging era of Industry 4.0, ML algorithms yield the power of AI to massively ubiquitous Internet-of-Things (IoT) devices. Applications in this field become smarter and more profitable as the availability of big data gets expanded, driving evolution of many aspects in science, industry, and daily life. However, state-of-the-art ML algorithms, specially Spiking Neural Networks (SNNs) and Convolutional Neural Networks (CNNs), represent elevated computational and energy cost. Therefore, hardware efficiency is one of the major goals to innovate compute engines as they are the machinery of the future.

Energy, performance, and chip-area are the key design concerns in computer systems. Considering the intrinsic error resilience of ML algorithms, paradigms such as approximate computing come to the rescue by offering promising efficiency gains to assist the aforementioned design concerns. Approximation techniques are widely used in ML algorithms at the model-structure as well as at the hardware processing level. However, state-of-the-art methods do not sufficiently address accelerator designs for Artificial Neural Networks (ANNs), in particular with Floating-Point (FP) computation.

To sustain the continuous expansion of ML applications on cost-effective compute devices, approximate computing has the potential to gradually transform from a design alternative to an essential feature. This dissertation focuses on the investigation of design methodologies to exploit the intrinsic error resilience of ML algorithms to optimize high-quality FP inference in low-power embedded systems.

In the field of SNNs, this dissertation presents a hardware design methodology for low-power inference of Spike-by-Spike (SbS) neural networks targeting embedded applications. This ML algorithm provides noise robustness and reduced complexity compared to conventional SNN with Leaky Integrate and Fire (LIF) mechanism. However, SbS networks represent a memory footprint

and a computational cost unsuitable for embedded applications. To address this problem, this research exploits the intrinsic error resilience of Sbs to improve performance and to reduce hardware complexity by approximation. More precisely, it is designed a hardware module to compute vector dot-product based on approximate computing with configurable quality using hybrid custom FP and logarithmic number representations. This approach reduces computational run-time, memory footprint, and power dissipation while preserving inference accuracy. To demonstrate this approach, it is presented a design exploration flow with High-Level Synthesis (HLS) on a Field-Programmable Gate Array (FPGA). The proposed design accelerates run-time $20.5\times$ and reduces memory footprint $8\times$, with less than 0.5% of accuracy degradation without model retraining on a handwritten digit classification task.

In the field of CNNs, this dissertation presents a hardware design methodology for low-power inference targeting CNN sensor analytics applications. In this research, it is proposed the Hybrid-Float6 (HF6) quantization and its dedicated hardware processor. This design features an optimized FP Multiply-Accumulate Unit (MAC) by reducing the mantissa multiplication to a multiplexer-adder operation. The intrinsic error tolerance of neural networks is exploited to further reduce the hardware design with approximation on the subnormal number computation. To preserve model accuracy, it is presented a Quantization-Aware Training (QAT) method, which in some cases improves accuracy based on the regularization effect. This concept is demonstrated in a lightweight Tensor Processor (TP) implementing a pipelined vector dot-product to accelerate 2D convolution operations. For ML portability and backward compatibility, the custom FP representation is wrapped in the standard FP format. The proposed hardware/software architecture is integrated with TensorFlow (TF) Lite. The applicability of this approach is evaluated with a CNN-regression model for anomaly localization in a Structural Health Monitoring (SHM) application based on Acoustic Emissions (AEs). The embedded hardware/software framework is demonstrated on XC7Z007S, as the smallest Zynq-7000 System-on-Chip (SoC). The proposed implementation achieves a peak power efficiency and run-time acceleration of 5.7 GFLOPS/s/W and $48.3\times$, respectively.

The outcome of this dissertation aims to contribute to the rise of a sustainable next generation of energy efficient neural network processors with ML portability and high-accuracy as design requirements.

1.1. Preamble

1.1.1. Industry 4.0

Industry is a highly mechanized and automatized piece of an economy that produces goods. Since the beginning of industrialization, technological leaps have led to paradigm shifts, now called "industrial revolutions": from mechanization, electrification, and later, digitalization (the

1. Introduction

so-called 3rd industrial revolution). Based on the advanced digitalization within factories, the combination of Internet technologies and future-oriented technologies in the field of "smart" things (machines and products) seems to result in a new fundamental paradigm shift in industrial production. Emerging from this future expectation, the term "Industry 4.0" was established for an expected "4th industrial revolution" [1].

1.1.2. Internet-of-Things in Industry

To build the emerging environment of Industry 4.0, disruptive technologies are required to handle autonomous communications between all industrial embedded computers throughout the factory and the Internet. Such technologies offer the potential to transform the industry along the entire production chain and stimulate productivity and overall economic growth [2]. These technologies include cloud computing, big data, and specially a new generation of IoT devices fused with Cyber-Physical Systems (CPS), safety-security, augmented reality, ML, and hardware accelerators [3].

1.1.3. Artificial Intelligence in Internet-of-Things

The continuous evolution of AI algorithms and IoT devices has not only made AI the major workload running on these embedded devices, but AI is becoming the main approach for industrial solutions, especially in the rise of Industry 4.0 [3]. There is a clear motivation to run AI/ML algorithms on IoT devices because of [4]: (1) feasibility of mission-critical with real-time processing; (2) privacy and security of data; (3) offline operation capability; and (4) robustness for stressed communication. Hence, the term of IoT has also been redefined as AI of Things (AIoT) to emphasize the impact of AI/ML on this technology [5].

1.1.4. Error Tolerance in Machine Learning Algorithms

An algorithm can be regarded as error-tolerant or error-resilient when it provides a result with the required accuracy while utilizing processing components with a certain degree of inaccuracy. There are several reasons why an algorithm/application is tolerant of errors as discussed in [6]. These include noisy or redundant data of the algorithm, approximate or probabilistic computations within the algorithm, and a range of acceptable outcomes. This is the case of ML models for AI applications.

1.2. Problem Statement

The problem lies in the fact that state-of-the-art AI/ML models, particularly CNNs and ANNs, are highly computational and data intensive. This brings significant challenges across the spectrum of computing hardware, specially in the scope of embedded systems [7]. The most deployed models and also the most computationally and energy expensive are for computer vision using CNNs. Compared to the conventional image processing methods, the accuracy of CNN has improved significantly that by 2015, a human can no longer beat a computer in image classification [4]. The early development of CNNs before 2016 mainly focused on accuracy improvement without considering computational costs. While accuracy of deep CNN for image classification improved 24% between 2012 and 2016, the demand on hardware resources increased more than 10 \times . Starting from 2017, significant attention was paid to improve hardware efficiency in terms of compute power, memory bandwidth, and power consumption, while maintaining accuracy at a similar level to human perception [7].

Consequently, the recent breakthroughs in AI/ML applications have brought significant advancements in neural network processors [8]. These rapid evolution, however, came at the cost of an important demand for computational power. Hence, to bring the inference speed to an acceptable level, Application-Specific Integrated Circuit (ASIC) with Neural Processing Unit (NPU) are becoming ubiquitous in both embedded and general purpose computing. NPUs perform several tera operations per second in a confined area, as a consequence, they become subject to elevated on-chip power densities that rapidly result in excessive on-chip temperatures during operation [9]. This outcome is expected on parallel computing techniques, yet unsustainable for resource-constrained devices. Therefore, radical changes to conventional computing are required in order to sustain and improve performance while satisfying energy and temperature constraints [10].

In the state-of-the-art research, we find plenty of hardware architectures for CNN accelerators implemented in FPGA. Most of the research implements fixed-point quantization, and very limited research focuses on FP. Moreover, to the best of our knowledge, there is no research work exploring custom or conventional FP inference for low-power embedded systems.

1.3. Research Objective

The main objective for this doctoral research is investigating hardware design methodologies for low-power FP neural network accelerators based on approximate computing with high quality of inference in the scope of embedded systems.

1.4. Working Hypothesis

To overcome the problem, based on the error resilience of ML algorithms, an evident solution is approximate computing. This paradigm has been used in a wide range of applications to increase hardware efficiency [11]. For neural network applications, two main approximation strategies are used, namely network compression and classical approximate computing [12].

1.4.1. Network Compression and Quantization

Researchers focusing on embedded applications started lowering the precision of weights and activation maps to shrink the memory footprint of the large number of parameters representing ANNs, a method known as network quantization. In this manner, reduced bit precision causes a small accuracy loss [13, 14, 15, 16]. In addition to quantization, network pruning reduces the model size by removing structural portions of the parameters and its associated computations [17, 18]. This method has been identified as an effective technique to improve the efficiency of CNN for applications with limited computational budget [19, 20, 21]. These techniques leverage the intrinsic error-tolerance of neural networks, as well as their ability to recover from accuracy degradation while training.

1.4.2. Approximate Computing

Approximate computing is a design paradigm that is able to tradeoff computation quality (e.g., accuracy) and computational efficiency (e.g., in run-time, chip-area, and/or energy) by exploiting the error resilience of applications/algorithms [10, 22]. Data redundancy of neural networks incorporate a certain degree of resilience against random external and internal perturbations; for instance, noisy inputs and random hardware errors. This property can be exploited in a cross-layer resilience approach [23]: by leveraging error tolerance at algorithmic-level, it can be allowed a certain degree of inaccuracies at the computing-level. This approach consists of designing processing elements that approximate their computation by employing cleverly modified algorithmic logic units [11].

Approximate computing techniques allow substantial enhancement in processing efficiency with moderated accuracy degradation. Some research papers have shown the feasibility of applying approximate computing to the inference stage of neural networks [24, 11, 25, 26, 27, 28]. Such techniques usually demonstrated small inference accuracy degradation, but significant enhancement in computational performance, chip-area, and energy consumption. Hence, by taking advantage of the intrinsic error-tolerance of neural networks, approximate computing is

positioned as a promising approach for inference on resource-limited devices. Nonetheless, the complex state-of-the-art of FP CNN inference has not been sufficiently explored with approximate computing techniques.

1.5. Motivation

The use of AI/ML is entering a new era with ubiquitous embedded connected devices. This transformation requires design techniques that reconcile accurate results with cost-effective and energy-efficient system architectures, since state-of-the-art AI/ML algorithms represent high computational and energy costs. This compromises the sustainability of the progressive expansion towards massive ubiquitous AI. Therefore, hardware efficiency is one of the major goals to innovate compute engines. This section presents the motivations to investigate design methodologies for low-power hardware acceleration for SbS and CNNs.

- **Spike-by-Spike Neural Networks.** SNNs offer advantageous robustness and the potential to achieve a power efficiency closer to that of the human brain. SNNs operate reliably using stochastic elements that are inherently non-reliable mechanisms [29]. This provides superior resistance against adversary attacks [30, 31]. Beside robustness, SNNs have further advantages like the possibility of a more efficient asynchronous parallelization and higher energy efficiency than conventional ANNs.

The Spike-by-Spike model is on the less realistic side of the SNN scale of biological realism [32, 30]. Consequently, the hardware complexity of SbS network implementations is greatly reduced [33]. In spite of this, SbS still uses stochastic spikes as a means of transmitting information between populations of neurons and thus retains the advantageous robustness of SNNs. A significant research effort has been done in SNN accelerators, see e.g. [34, 12, 35, 36, 37, 38].

However, hardware accelerators that focus on SbS have only been partially investigated so far [33]. Enhanced SbS accelerators will have a double impact. From scientific and application point of view, they will facilitate fundamental research for neuroscience [30, 39, 40] and contribute to the deployment of robust neural networks in small embedded systems [41].

- **Convolutional Neural Networks.** CNNs represent the essential building blocks in 2D pattern analytics. Sensor-based applications such as mechanical fault detection [42, 43], structural health monitoring [44], Human Activity Recognition (HAR) [45], hazardous gas

1. *Introduction*

detection [46] have been powered by CNN models in industry and academia. CNN models provide advantages such as local dependency, scale invariance, and noise resilience in analytics [25]. However, these models are computationally intensive and power-hungry. This is particularly challenging for low-power embedded applications, specially in the field of IoT. As a result, numerous commercial ASIC and FPGA accelerators have been proposed, these are targeting both High Performance Computing (HPC) for data-centers and embedded systems applications.

However, most accelerators have been implemented to target mid- to high-range FPGAs for computationally intensive CNN models such as AlexNet, VGG-16, and ResNet-18. The main drawbacks of these implementations are power supply demands, physical dimensions, heat sink requirements, air cooling, and a resulting high price. In some cases, these implementations are not feasible for ubiquitous low-power/resource-constrained applications. Furthermore, reducing the compute hardware with aggressive quantization such as binary [13], ternary [47], and mixed precision (2-bit activations and ternary weights) [48] typically incur significant accuracy degradation for very low precisions, especially for complex problems[49].

1.6. Main Contribution

This thesis contributes to hardware design methodologies for custom floating-point neural network accelerators for high quality of inference in low-power embedded systems. The contributions for SbS and CNN hardware accelerators are listed below.

1.6.1. Spike-by-Spike Neural Networks

1. It is presented a hardware component for FP vector dot-product approximation. This design increases the performance of computation by performing element-wise multiplication with a quality configurable design based on bit truncation and denormalized accumulation.
2. It is presented a design exploration with the proposed dot-product approximation using synaptic weight vectors with custom FP and logarithmic representation. The run-time, accuracy degradation, resource utilization, and power dissipation are evaluated. Experimental results demonstrate 20.5 \times latency enhancement versus embedded Central Processing Unit (CPU) (ARM Cortex-A9 at 666MHz), and less than 0.5% of accuracy degradation on a handwritten digit recognition task (MNIST).

3. It is proposed a noise tolerance plot as quality monitor, which serves as an intuitive visual model to provide insights into the accuracy degradation of SbS networks under approximate processing effects.
4. The presented design for FP dot-product approximation is adaptable as a building block for other error resilient applications (e.g., image/video processing).

1.6.2. Convolutional Neural Networks

1. It is proposed the HF6 quantization and its dedicated hardware architecture. This design features an optimized hardware MAC by reducing the mantissa multiplication to a multiplexer-adder operation. This approach exploits the intrinsic error tolerance of ANN to further reduce the hardware design with approximation. To preserve model accuracy, it is presented a quantization-aware training method, which in some cases improves accuracy based on the regularization effect.
2. It is developed a custom hardware/software co-design framework for CNN sensor analytics applications on low-power and resource-constrained embedded FPGAs. This architecture integrates TensorFlow Lite.
3. It is presented a customizable tensor processor as a dedicated hardware for HF6. This design computes *Conv2D* tensor operations employing a pipelined vector dot-product with approximate computing and parametrized on-chip memory utilization.
4. The potential of this approach is demonstrated with a CNN-regression model for anomaly localization in structural health monitoring based on acoustic emissions. A hardware design exploration is addressed evaluating accuracy, compute performance, hardware resource utilization, and energy consumption.

1.7. Publications

The outcome of this dissertation, including the collaborative works with our research partners is a list of publications including [41, 50, 51]. In the following, a complete list of the related publications are itemized.

1.8. Dissertation Outline

This dissertation is organized in three main parts: an introduction, where the state of the art and related background are stated; a central core, where the proposed design methodologies and validation are presented; and a final part with the conclusion. More precisely:

I Introduction: Chapter 2 introduces the background related to SbS, CNN, and FP number representation.

II Core: the proposed hardware design methodologies for SbS and CNN accelerators are presented in Chapter 3 and Chapter 4, respectively.

III Conclusions: the final conclusions are presented in Chapter 5.

2.1. Spike-by-Spike Neural Networks

Technically, SbS is a spiking neural network based on a generative probabilistic model. It iteratively finds an estimate of its input probability distribution $p(s)$ (i.e. the probability of input node s to stochastically send a spike) by its latent variables via $r(s) = \sum_i h(i)W(s|i)$, where \vec{h} is an inference population composed of a group of neurons that compete with each other. An Inference Population (IP) sees only the spikes s_t (i.e. the index identifying the input neuron s which generated that spike at time t produced by its input neurons, not the underlying input probability distribution $p(s)$ itself. By counting the spikes arriving at a group of SbS neurons, $p(s)$ is estimated by $\hat{p}(s) = 1/T \sum_t \delta_{s,s^t}$ after T spikes have been observed in total. The goal is to generate an internal representation $r(s)$ from the string of incoming spikes s_t such that the negative logarithm of the likelihood $L = C - \sum_\mu \sum_s \hat{p}_\mu(s) \log(r_\mu(s))$ is minimized. C is a constant which is independent of the internal representation $r_\mu(s)$ and μ denotes one input pattern from an ensemble of input patterns. Applying a multiplicative gradient descent method on L , an algorithm for iteratively updating $h_\mu(i)$ with every observed input spike s_t could be derived [30]:

$$h_\mu^{new}(i) = \frac{1}{1 + \epsilon} \left(h_\mu(i) + \epsilon \frac{h_\mu(i)W(s_t|i)}{\sum_j h_\mu(j)W(s_t|j)} \right) \quad (2.1)$$

2. Background

where ϵ is a parameter that also controls the strength of sparseness of the distribution of latent variables $h_\mu(i)$. Furthermore, L can also be used to derive online and batch learning rules for optimizing the weights $W(s|i)$. The interested reader is referred to [30] for a more detailed exposition.

From a practical point of view, SbS provides a mechanism to obtain a sparse representation of input patterns. Given a set of training samples $\{x_\eta\}$, it learns weights (W), that allow to express the input patterns as a linear sparse non-negative combination of features. During inference, it provides a mechanism for expressing each test input x_μ as $x_\mu \approx W h_\mu$ where all entries are non-negative.

The inference procedure consists in generating indices s_t distributed according to a categorical distribution of the input pattern $s_t \sim \text{Categorical}(x_\mu(0), x_\mu(1), \dots, x_\mu(N - 1))$. Starting with a random h and executing iteratively **Eq.** (2.1) the SbS algorithms finds h_μ . The fundamental concept of SbS can be extended from vector to matrix inputs. In this case, the linear operation $W h_\mu$ can be replaced by a convolution to obtain a convolutional SbS layer. A detailed description of the SbS algorithm is presented in the Appendix A

2.1.1. Basic Network Overview

SbS network models can be constructed in sequential layered structures [32]. Each layer consists of many IPs (represented by \vec{h}), while the communication between them is organized by a low bandwidth signal – the spikes.

The SbS layer update is summarized in Algorithm 1. This is an iterative algorithm, where the number of spikes are denoted as (N_{Spk}) , which is the number of iterations. As a generative model, each iteration updates the internal representation (H) based on the input spikes (S_t^{in}). A basic SbS network architecture for handwritten digit classification (MNIST) is shown in **Fig.** 2.1 and **Tab.** 2.1. Each IP is an independent computational entity, this allows to design specialized hardware architectures that can be massively parallelized (see **Fig.** 2.2).

2.1.2. Computational Cost

The number of MAC operations required for inference of an SbS layer is defined by $NOPS_{MAC} = N_{Spk} N_X N_Y K_X K_Y (3N_H + 2)$, where N_{Spk} is the number of spikes (iterations), $N_X N_Y$ is the size of the layer, $K_X K_Y$ is the size of the kernel for convolution/pooling, and N_H is the length of \vec{h} . The computational cost of SbS network models is higher compared to equivalent CNN models and lower compared to regular SNN models (e.g., LIF) [52].

Algorithm 1: SbS layer update.

```

1: for  $t \leftarrow 0$  to  $N_{Spk} - 1$  do
2:   for  $x \leftarrow 0, y \leftarrow 0$  to  $N_X - 1, N_Y - 1$  do
3:      $S_t^{out}(x, y) \sim \text{Categorical}(H(x, y, :))$ 
4:     for  $\Delta_X \leftarrow 0, \Delta_Y \leftarrow 0$  to  $K_X - 1, K_Y - 1$  do
5:        $spk \leftarrow S_t^{in}(x + \Delta_X, y + \Delta_Y)$ 
6:       for  $i \leftarrow 0$  to  $N_H - 1$  do
7:          $\Delta h(i) \leftarrow H(x, y, i) \cdot W(\Delta_X, \Delta_Y, spk, i)$ 
8:          $r \leftarrow r + \Delta h(i)$ 
9:       end for
10:      for  $i \leftarrow 0$  to  $N_H - 1$  do
11:         $H^{new}(x, y, i) \leftarrow \frac{1}{1+\epsilon} (H(x, y, i) + \frac{\epsilon}{r} \Delta h(i))$ 
12:      end for
13:    end for
14:  end for
15: end for

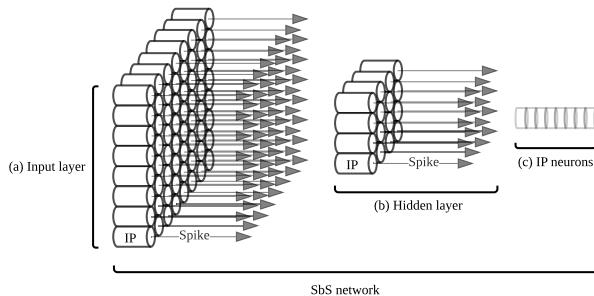

Figure 2.2.: SbS IPs as independent computational entities, (a) illustrates an input layer with a massive amount of IPs operating as independent computational entities, (b) shows a hidden layer with an arbitrary amount of IPs as independent computational entities, (c) exhibits a set of neurons grouped in an IP.

2. Background

Table 2.1.: SbS network architecture for handwritten digit classification task.

Layer (H^l)	Layer size			Kernel size	
	N_X	N_Y	N_H	K_X	K_Y
Input (H^X)	28	28	2	-	-
Convolution (H^1)	24	24	32	5	5
Pooling (H^2)	12	12	32	2	2
Convolution (H^3)	8	8	64	5	5
Pooling (H^4)	4	4	64	2	2
Fully connected (H^5)	1	1	1024	4	4
Output (H^Y)	1	1	10	1	1

2.1.3. Error Tolerance

To illustrate the error tolerance of SbS networks, it is presented a classification performance under positive additive uniformly distributed noise as external disturbance. **Fig. 2.3** presents a comparison of the classification performance of an SbS network and a standard CNN, with the same amount of neurons per layer as well as the same layer structure. Both neural networks are trained for handwritten digit classification on MNIST dataset [53] (see [32] for details). The figure shows the correctness for the MNIST test set with its 10,000 patterns in dependency of the noise level for positive additive uniformly distributed noise. The blue curve shows the performance for the CNN, while the red curve shows the performance for the SbS network with 1200 spikes (iterations). Beginning with a noise level of 0.1, the respective performances are different with a p - level of at least 10^{-6} (tested with the Fisher exact test). Increasing the number of spikes per SbS population to 6000 (performance values shown as black stars), shows that more spikes can improve the performance under noise even more.

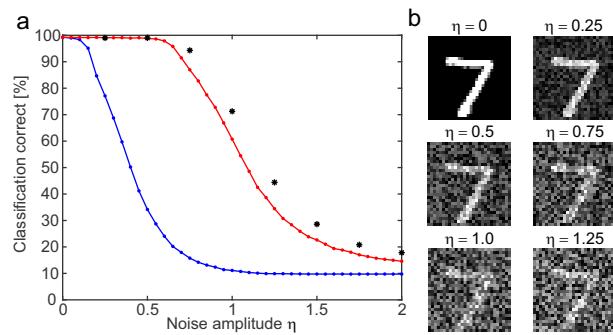

Figure 2.3.: (a) Performance classification of SbS NN versus equivalent CNN, and (b) example of the first pattern in the MNIST test data set with different amounts of positive additive uniformly distributed noise.

2.2. Conv2D Tensor Operation

A convolutional layer aims to learn and extract feature representations from an input. Each unit of a feature map is connected to a region of neighboring units on the input maps (from the previous layer). This neighborhood in the previous layer is known as the receptive field of such unit. A new feature map can be obtained by first convolving the input maps with a learned kernel and then applying a nonlinear elementwise activation function to the convolved results. All spatial locations on the input maps share a kernel to generate a feature map. All feature maps are obtained by convolving several different kernels [54].

The 2D convolution process is performed by the *Conv2D* tensor operation, described in **Eq.** (2.2), where h is the input tensor containing the feature maps, W is the convolution kernels (known as filters), and b is the bias vector for the output feature maps [55]. $K \times L \times M$ is the receptive field size, $K \times L$ is the convolution kernel, and M is the number of input channels/feature maps. In this work, the *Conv* is denoted as *Conv2D* operator.

$$\text{Conv}(W, h)_{i,j,o} = \sum_{k,l,m}^{K,L,M} h_{(i+k,j+l,m)} W_{(o,k,l,m)} + b_o \quad (2.2)$$

2.3. Floating-point Number Representation

The representation of every numerical value, in any numerical system, is made of an integer and a fractional part. The border that delimits them is called the radix point. The fixed-point format for representing numeric values derives its name from the fact that in this format, the base point is fixed at a certain position. For integer numbers, this position is at the right of the least significant digit.

In scientific computation, it is often necessary to represent very large and very small values. This is difficult to achieve using the fixed-point format because the bit size required to maintain both the desired precision and the desired range are very large. In such situations, FP formats are used to represent real numbers. Each FP number can be divided into three fields: sign S , exponent E , and mantissa M . Using the binary number system, it is possible to represent any FP number as:

$$(-1)^S \times 1.M \times 2^{E-B} \quad (2.3)$$

In FP representations the exponent is biased. This bias depends on the bit size of the exponent

2. Background

field. This exponent bias is defined by **Eq.** (2.4), where E_{size} is the exponent bit size.

$$B = 2^{E_{size}-1} - 1 \quad (2.4)$$

There is a natural trade-off between small bit size requiring fewer hardware resources and larger bit size providing higher precision. Within a given total bit size, it is possible to assign various combinations of sizes to the exponent and mantissa fields, with wider exponents resulting in a higher range and wider mantissa resulting in better precision.

The most widely used format for FP arithmetic is the IEEE 754 standard [56]. The IEEE single-precision format (32-bit) is expressed by **Eq.** (2.3) with $B = 127$, 8 bits for the exponent and 23 bits for the mantissa, see **Fig. 2.4(a)**. In FP formats, the numbers are normalized, the leading one is an implicit bit, and only the fractional part is explicitly stored in the mantissa field.

Reduced bit size than those specified in the IEEE 754 standard are often sufficient to provide the desired precision. Reduced designs require fewer hardware resources enabling low-power implementations. In custom hardware designs, it is possible to customize the FP format implemented. In later sections, the term $EaMb$ is used to denote FP formats, where a and b are the exponent and mantissa bit size, respectively. For example, E4M1 means 4-bit exponent and 1-bit mantissa, see **Fig. 2.4(d)**.

There are three special definitions in IEEE 754 standard. The first is subnormal numbers when $E = 0$, then **Eq.** (2.3) is modified to **Eq.** (2.5). Infinity and Not a Number (NaN) are the other two special cases but are not used in our work.

$$(-1)^S \times 0.M \times 2^{1-B} \quad (2.5)$$

3.1. Introduction

The exponential improvement in computing performance and the availability of large amounts of data are boosting the use of AI applications in our daily lives. Among the various algorithms developed over the years, neural networks have demonstrated remarkable performance in a variety of image, video, audio, and text analytics [57, 58].

3. Accelerating Spike-by-Spike Neural Networks

Historically, ANNs can be classified into three different generations [59]: the first one is represented by the classical McCulloch and Pitts neuron model using discrete binary values as outputs; the second one is represented by more complex architectures as Multi-Layer Perceptron (MLP) and CNN using continuous activation functions; while the third generation is represented by SNN using spikes as means for information exchange between groups of neurons. Although the AI research is currently dominated by Deep Neural Networks (DNNs) from the second generation, the SNNs belonging to the third generation are receiving considerable attention [37, 30, 59, 60].

SNNs offer advantageous robustness and the potential to achieve power efficiency closer to that of the human brain. SNNs operate reliably using stochastic elements that are inherently non-reliable mechanisms [29]. This provides superior resistance against adversary attacks [30, 31]. Beside robustness, SNNs have further advantages like the possibility of a more efficient asynchronous parallelization and higher energy efficiency than DNNs. For example, Loihi [38], a SNN developed by Intel, can solve LASSO optimization problems with an over three orders of magnitude better energy-delay product than conventional approaches. These advantages are motivating large research programs by major companies (e.g., Intel [38] and IBM [36]) as well as pan-european projects in the domain of spiking neural networks [37].

SNNs emulate the real behavior of neurons in different levels of detail. The more detailed the biological part is emulated, the greater the computational complexity [52, 61]. For example, LIF is a widely used model; however, this model is relatively more complex for emulation in low-power embedded applications.

Alternatively, the SbS neural network is a remarkable model for its reduced complexity, which is on the less realistic side of the SNN scale of biological realism [32, 30]. Consequently, the hardware complexity of SbS network implementations is reduced [41, 33]. In spite of this, SbS still uses stochastic spikes as a means of transmitting information between populations of neurons and thus retains the advantageous robustness of SNNs.

The conceptual model in SbS (see Chapter 2.1 for a review) differs fundamentally from conventional ANNs since (a) the building blocks of the network are IPs which are an optimized generative representation with non-negative values, (b) time progresses from one spike to the next, preserving the property of stochastically firing neurons, and (c) a network has only a small number of parameters, which is a noise-robust stochastic version of Non-Negative Matrix Factorization (NNMF). The SbS network is placed between non-spiking Neural Networks (NNs) and stochastically spiking NNs, which offers advantages from both structures [32]. On one hand, the SbS model incorporates the inherent robustness of SNNs, which gives the possibility of more efficient asynchronous parallelization and resilience against disturbances based on the synaptic stochasticity; on the other hand, the SbS model incorporates the regular flow of information from

CNNs.

As computational demanding algorithms, CNNs and SNNs in particular, must be addressed by specialized hardware architectures. A significant research effort has been performed in SNN accelerators, see e.g. [34, 12, 35, 36, 37, 38]. However, hardware accelerators that focus on SbS have only been partially investigated so far [33]. Enhancing SbS accelerators will contribute to the deployment of robust neural networks in resource-constrained devices [41, 30, 39, 40].

A central point that can be optimized in current SbS accelerators is the use of approximation techniques. Most SNN models use FP numerical representation, which imposes high complexity of the required circuits for FP operations. Quantization has the potential to improve computational performance; however, this solution is often accompanied by quantization-aware training methods that, in some cases, are problematic or even inaccessible, particularly in deep SNN algorithms [62].

As an alternative, based on the relaxed need for fully precise or deterministic computation of neural networks, approximate computing techniques allow substantial enhancement in processing efficiency with moderated accuracy degradation. Some research papers have shown the feasibility of applying approximate computing to the inference stage of neural networks [24, 27, 26, 25]. Such techniques usually demonstrated small inference accuracy degradation, but significant enhancement in computational performance, chip-area, and energy consumption. Hence, by taking advantage of the intrinsic error-tolerance of neural networks, approximate computing is positioned as a promising approach for inference on resource-limited devices.

In this chapter, it is presented an accelerator for SbS neural networks with a dot-product hardware design based on approximate computing with hybrid custom FP and logarithmic number representation. This hardware unit has a quality configurable scheme based on the exponent and mantissa bit-size of the synaptic-weight vector. **Fig. 3.1** illustrates the dot-product hardware module with standard FP (IEEE 754) arithmetic, and our approach with hybrid custom FP as well as logarithmic approximation. As a design parameter, the mantissa bit-width of the weight vector provides a tunable knob to trade-off between efficiency and Quality of Result (QoR) [63, 11]. Since the lower-order bits have smaller significance than the higher-order bits, bit-truncation strategy represents a minor impact on QoR [64, 65]. Further on, the mantissa bits can be completely removed in order to use only the exponent of a FP representation. This configuration becomes a logarithmic representation, which consequently leads to significant architectural-level optimizations using only hardware adders and shifters for dot-product approximation. Moreover, since approximations and noise have qualitatively the same effect [66], it is proposed the noise tolerance plot as an intuitive visual measure to provide insights into the quality degradation and

3. Accelerating Spike-by-Spike Neural Networks

resilience budget of SbS networks under approximation effects.

The main contributions presented in this chapter are as follows:

- A hardware module for dot-product approximation. To perform the sum of pairwise products of two vectors, this hardware module has the following three design features: (1) the pairwise product is approximated by adding integer exponents and multiplying truncated mantissas, and the sum of products is done by accumulating denormalized integer products with barrel shifters, this increases computational throughput; (2) the synaptic weight vector uses either reduced custom FP or logarithmic representation, this reduces memory footprint; and (3) the neuron vector uses either standard or custom FP representation, this preserves QoR and overall inference accuracy.
- A hardware design exploration with the proposed dot-product approximation using synaptic weight vectors with custom FP and logarithmic representation as shown in **Fig. 3.1**. It is presented the inference run-time, accuracy degradation, resource utilization and power dissipation. Experimental results demonstrate $20.5\times$ run-time enhancement versus embedded CPU (ARM Cortex-A9 at 666 MHz), and less than 0.5% of accuracy degradation without retraining on a handwritten digit recognition task (MNIST). This machine learning task simply provides a proof of concept to demonstrate the feasibility of our approximation technique for SbS neural network accelerators.

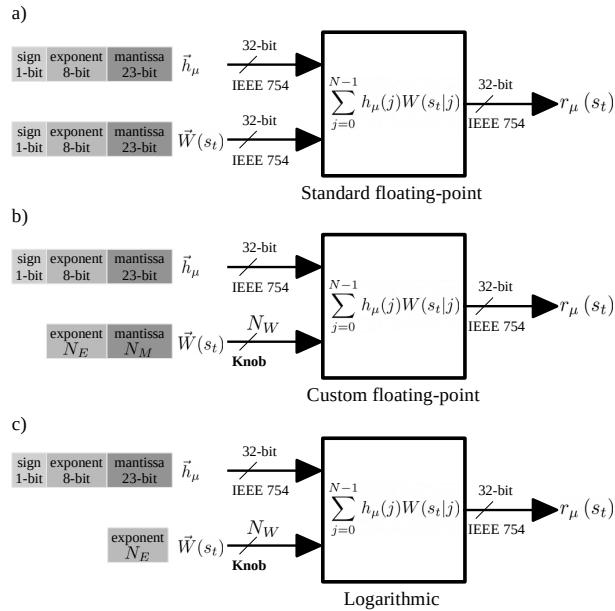

Figure 3.1.: Dot-product hardware module with (a) standard floating-point (IEEE 754) arithmetic, (b) hybrid custom floating-point approximation, and (c) hybrid logarithmic approximation.

- A noise tolerance plot is proposed as quality monitor, which serves as an intuitive visual model to provide insights into the accuracy degradation and noise resilience-budget of SbS networks under approximate processing effects.
- The present design for dot-product approximation is adaptable as a building block for other error resilient applications (e.g., image/video processing).

To promote the research on SbS networks, the design exploration framework is made available to the public as an open-source project at <https://github.com/YaribNevarez/sbs-framework.git>

3.2. Related Work

For efficient neural network computation, two main optimization strategies are used, namely network compression and classical approximate computing [12].

3.2.1. Network Compression

Researchers focusing on embedded applications started lowering the precision of weights and activation maps to shrink the memory footprint of the large number of parameters representing ANNs, a method known as network compression or quantization. This practice takes advantage of the intrinsic error-tolerance of neural networks, as well as their ability to compensate for approximation while training. In this way, reduced bit precision causes a small accuracy loss [13, 14, 15, 16].

In hardware development, Weight Quantization (WQ) has shown up to $2\times$ improvement in energy consumption with an accuracy degradation of less than 1% [67, 68]. Some advanced quantization methods yield to Binary Neural Networks (BNNs) allowing the use of Logical Exclusive Non-Disjunctions (XNORs) instead of the conventional costly MACs [16]. In [69], Sun et al. report an accuracy of 98.43% on handwritten digit classification (MNIST) with a simple BNN. Hence, quantization is a powerful tool for improving the energy efficiency and memory requirements of ANN accelerators, with limited accuracy degradation.

In addition to quantization, network pruning reduces the model size by removing structural portions of the parameters and its associated computations [17, 18]. This method has been identified as an effective technique to improve the efficiency of DNN for applications with limited computational budget [19, 20, 21].

These methods can be used for SNNs as well. In [70], Rathi et al. report up to $3.1\times$ improvement in energy consumption with an accuracy loss of around 3%. Weight quantization

3. Accelerating Spike-by-Spike Neural Networks

allows the designer to realize a trade-off between the accuracy of the SNN application and efficiency of resources. Approximate computing can also be applied at the neuron level, where irrelevant units are deactivated to reduce the computation cost of the SNNs [71]. This computation skipping can be applied randomly on synapses, training ANNs with stochastic synapses improves generalization, resulting in a better accuracy [72, 73]. Such methods are compatible with SNNs and have been tested both during training [74, 75] and operation [76], and even to define the connectivity between layers [77, 78]. Implementations of spiking neuromorphic systems in FPGA [79] and hardware [80] demonstrated that synaptic stochasticity allows to increase the final accuracy of the networks while reducing memory footprint.

Quantization is therefore a powerful technique to improve energy efficiency and memory requirements of ANN and SNN accelerators, with small accuracy degradation. However, this approach requires quantization-aware training methods that, in some cases, are problematic or even inaccessible, particularly in emerging deep SNN algorithms [62].

3.2.2. Classical Approximate Computing

Approximate computing has been used in a wide range of applications to increase the computational efficiency in hardware [11]. This approach consists of designing processing elements that approximate their computation by employing modified algorithmic logic units [11]. In [81], Kim et al. have shown SNNs using carry skip adders achieving 2.4 \times latency enhancement and 43% more energy efficiency, with an accuracy degradation of 0.97% on a handwritten digit classification task (MNIST). Therefore, approximate computing provides important enhancement in energy efficiency and processing speed.

However, as the complexity of the dataset increases, as well as the depth of the network topology, such as ResNet [82] on ImageNet [83], the accuracy degradation becomes more important and may not be negligible anymore [16], especially for critical applications such as autonomous driving. Therefore, it is not certain that network compression techniques and approximate computing are suitable for all applications.

3.2.3. Spike-by-Spike Neural Networks Accelerators

Rotermund et al. demonstrated the feasibility of a neuromorphic SbS IP on a Xilinx Virtex 6 FPGA [33]. It provides a massively parallel architecture, optimized to reduce memory access and suitable for ASIC implementations. Nonetheless, this design is considerably resource-demanding if implemented as a full SbS network in today's embedded technology.

3.3. System Design

In this section, it is presented a hardware architecture composed of specialized heterogeneous Processing Units (PUs) with hybrid custom floating-point and logarithmic dot-product approximation. This approach represents an advantageous design for error resilient applications in resource-constrained devices due to the reduced hardware utilization and memory footprint. Furthermore, the proposed approach allows the implementation of stationary synaptic weight matrices as internal accelerator storage based on the reduced memory footprint.

Regarding the software architecture, this is structured as a layered object-oriented application framework written in the C programming language. This offers a comprehensive high level embedded software Application Programming Interface (API) that allows the construction of scalable sequential SbS networks with configurable hardware acceleration. Conceptually this design is modular, reusable, and extensible. The overall structure is depicted in **Fig. 3.2**.

3.3.1. Hardware Architecture

As a hardware/software co-design, the system architecture is an embedded CPU+FPGA-based platform, where the acceleration of SbS network computation is based on asynchronous¹ execution of parallel heterogeneous processing units: *Spike* (input layer), *Conv* (convolution), *Pool* (pooling), and *FC* (fully connected). **Fig. 3.3** illustrates the system overview as a scalable structure. For hyperparameter configuration, each PU uses AXI-Lite interface. For data transfer, each PU uses AXI-Stream interfaces via Direct Memory Access (DMA) allowing data movement with high transfer rate. Each PU asserts an interrupt flag once the job or transaction is complete. This interrupt event is handled by the embedded CPU to collect results and start a new transaction.

¹The system is synchronous at the circuit level, but the execution is asynchronous in terms of jobs.

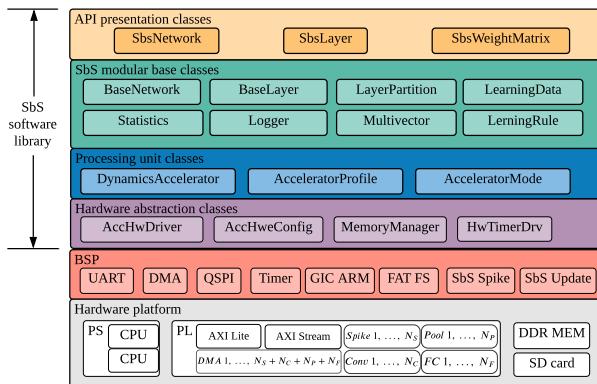

Figure 3.2.: System-level overview of the embedded software architecture.

The hardware architecture can resize its resource utilization by changing the number of PU instances prior to the hardware synthesis, this provides scalability with a good trade-off between area and throughput. The dedicated PUs for *Conv* and *FC* implement the proposed dot-product approximation as a system component. The PUs are written in System C using Xilinx Vivado HLS. In this research, we illustrate the integration of the approximate dot-product component on the *Conv* PU.

3.3.2. Conv Processing Unit

This hardware module computes the dynamics of the IP defined by Eq. (2.1) and offers two modes of operation: *configuration* and *computation*.

Configuration Mode

In this mode of operation, the PU receives and stores in on-chip memory (BRAM) the hyperparameters to compute the IP dynamics: ϵ as the epsilon, N as the length of $\vec{h}_\mu \in \mathbb{R}^N$, $K \in \mathbb{N}$ as the size of the convolution kernel, and $H \in \mathbb{N}$ as the number of IPs to process per transaction. H is the number of IPs forming a layer or a partition.

Additionally, the processing unit also stores in on-chip memory (BRAM) the synaptic weight matrix using a number representation with a reduced memory footprint. Fundamentally, the synaptic weight matrix is defined by $W \in \mathbb{R}^{K \times K \times M \times N}$ with $0 \leq W(s_t|j) \leq 1$ and $\sum_{s_t=0}^{M-1} W(s_t|j) = 1$ [32]. Hence, W employs only positive normalized real numbers. Therefore, W is deployed using a reduced floating-point or logarithmic representation as follows:

- Custom floating-point representation. In this case, W is deployed with a reduced floating-point representation using the designer defined bit-width for the exponent and for the man-

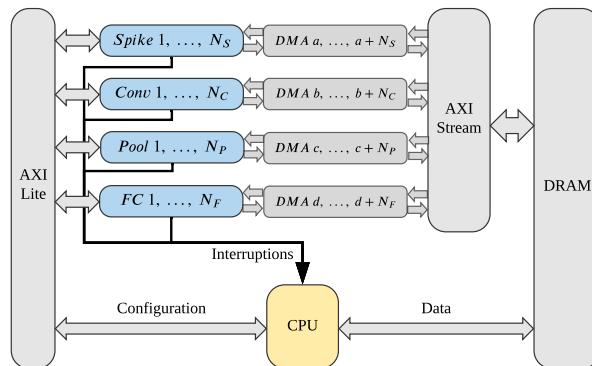

Figure 3.3.: System-level hardware architecture with scalable number of heterogeneous PUs: *Spike*, *Conv*, *Pool*, and *FC*

tissa. For example, 4-bit exponent, 1-bit mantissa; as a result: 5-bit custom floating-point. The proposed method to determine the required bit-width is described in Section 3.3.3.

- Logarithmic representation. In this case, the synaptic weight matrix is $W \in \mathbb{N}^{K \times K \times M \times N}$ with positive natural numbers. Since $0 \leq W(s_t|j) \leq 1$ and $\sum_{s_t=0}^{M-1} W(s_t|j) = 1$, W has only negative values in the logarithmic domain. Hence, the sign bit is omitted, and the values are represented as natural numbers. Therefore, W is deployed with a representation using the necessary bit-width for the exponent according to the given application. For example, 4-bit exponent. The method to determine the required bit-width is described in Section 3.3.3.

In order to deploy different SbS models, the *Conv* processing units can load different hyperparameters and synaptic weight matrices as required via the embedded software.

Computation Mode

In this mode of operation, the PU executes a transaction to process a group of IPs using the previously given hyperparameters and synaptic weight matrix. This process operates in six stages as shown in **Fig. 3.4**. In the first two stages, the PU receives $\vec{h}_\mu \in \mathbb{R}^N$, then the PU calculates the emitted spike and stores it in $S^{new} \in \mathbb{N}^H$ (output spike vector). From the third to the fifth stage, the PU receives $S_t \in \mathbb{N}^{K \times K}$ (input spike matrix), then it computes the update dynamics, and then it dispatches $\vec{h}_\mu^{new} \in \mathbb{R}^N$ (updated IP). This process repeats for H number of loops (for each IP of the layer or partition). Finally, S^{new} is dispatched.

The computation of the update dynamics (see **Fig. 3.4(d)**) operates in two stages or hardware modules: *dot-product* and *neuron update*. First, the *dot-product* module calculates the sum of pairwise products of \vec{h}_μ and $\vec{W}(s_t)$, each pairwise product is stored as intermediate results. Subsequently, the *neuron update* module calculates **Eq. (2.1)** reusing parameters and previous intermediate results.

The calculation of the dot-product of **Eq. (2.1)** represents a considerable computational cost using standard floating-point in non-quantized network models. Fortunately, the pair product of $h_\mu(j)$ and $W(s_t|j)$ was defined by us as an approximable factor in the dot-product of **Eq. (2.1)**. In the following section, we focus on an optimized dot-product hardware design based on approximate computing.

3.3.3. Dot-Product Hardware Module

The dot-product hardware module is part of an application-specific architecture optimized to approximate the dot-product of arbitrary length vectors, see **Eq. (3.1)**. For quality configurability,

3. Accelerating Spike-by-Spike Neural Networks

we parameterized the mantissa bit-width of $\vec{W}(s_t)$, which provides a tunable trade-off between resource utilization and QoR. Since the lower-order bits have smaller significance than the higher-order bits, removing them may have only a minor impact on QoR. We designate this as hybrid custom floating-point approximation (see **Fig. 3.1(b)**).

$$r_\mu(s_t) = \sum_{j=0}^{N-1} h_\mu(j) W(s_t|j) \quad (3.1)$$

Further on, we remove the mantissa bits completely in order to use only the exponent of a floating-point representation. Hence, the worst-case quality and yet the most efficient configuration becomes a logarithmic representation. Consequently, this structure leads to advantageous architectural optimizations using only adders and barrel shifters for dot-product approximation in hardware. We designate this as hybrid logarithmic approximation (see **Fig. 3.1(c)**).

In order to determine the required bit-width for the number representation, we use **Eq. (3.2)**, **Eq. (3.3)**, and **Eq. (3.4)**.

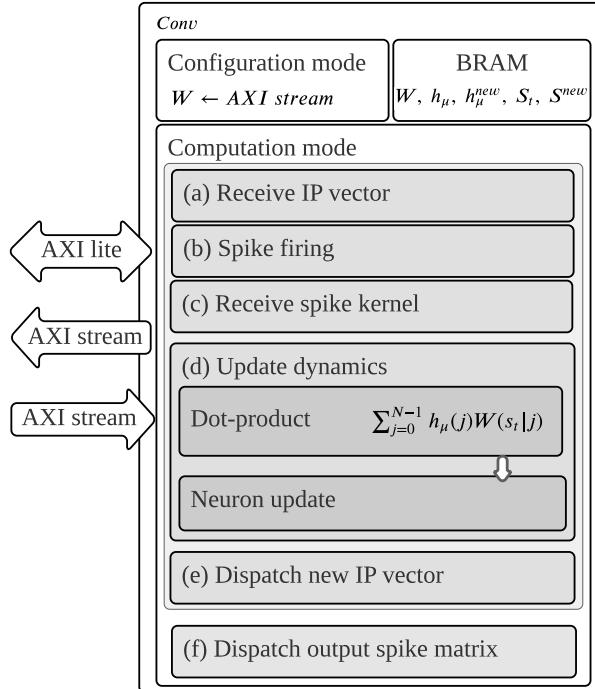

Figure 3.4.: The *Conv* processing unit and its six stages: (a) receive IP vector, (b) spike firing, (c) receive spike kernel, (d) update dynamics, (e) dispatch new IP vector, (f) dispatch output spike matrix.

$$E_{\min} = \log_2(\min_{\forall i}(W(i))) \quad (3.2)$$

$$N_E = \lceil \log_2(|E_{\min}|) \rceil \quad (3.3)$$

$$N_W = N_E + N_M \quad (3.4)$$

The **Eq.** (3.2) obtains the exponent of the minimum entry value in the synaptic weight matrix. Since $0 \leq W(s_t|j) \leq 1$ and $\sum_{s_t=0}^{M-1} W(s_t|j) = 1$, W has only negative values in the logarithmic domain; the smallest value is expressed by the biggest negative exponent (E_{\min}). Then, the **Eq.** (3.3) obtains the necessary bit-width to represent the exponent (N_E). Finally, we obtain the total bit-width by incorporating both exponent and mantissa bit-widths in **Eq.** (3.4). N_M denotes the mantissa bit-width, this is a knob parameter that is tuned by the designer to trade-off between resource utilization and QoR. The bit-width concept is illustrated in **Fig. 3.1**.

In this section, we will present three pipelined hardware modules with standard floating-point (IEEE 754) computation, hybrid custom floating-point approximation, and hybrid logarithmic approximation.

Dot-Product with Standard Floating-Point Computation

The hardware module to calculate the dot-product with standard floating-point computation is shown in **Fig. 3.5**. This diagram presents the hardware blocks and their clock cycle schedule. This module loads both $h_\mu(j)$ and $W(s|j)$ from BRAM, then the PU executes the pairwise product (**Fig. 3.5(c)**) and accumulation (**Fig. 3.5(d)**). Intermediate results of $h_\mu(j)W(s_t|j)$ are stored in BRAM for reuse in the neuron update stage. The latency in clock cycles of this hardware module is defined by **Eq.** (3.5), where N is the vector length of the dot-product. This equation is obtained from the general pipelined hardware latency formula: $L = (N - 1)II + IL$, where II is the initiation interval (**Fig. 3.5(a)**), and IL is the iteration latency (**Fig. 3.5(b)**). Both II and IL are obtained from the high-level synthesis analysis. The equation for the latency with standard 32-bit floating-point is:

$$L_{f32} = 10N + 9 \quad (3.5)$$

In this design, the high-level synthesis tool infers computational blocks with considerable latency cost for standard floating-point. In the case of floating-point multiplication (Fig. 3.5(c)), the synthesis infers a hardware block with a latency cost of 5 clock cycles. This block executes addition of exponents, multiplication of mantissas, and mantissa correction (when needed). Moreover, in the case of floating-point addition (3.5(d)), the synthesis infers a hardware block with a latency cost of 9 clock cycles. Seemingly, this block executes alignment of mantissas, addition, and correction (when needed). Therefore, the use of standard floating-point results in high computational cost, this represents unnecessary overhead in error tolerant applications.

Dot-Product with Hybrid Custom Floating-Point and Logarithmic Approximation

The hardware module to calculate dot-product with hybrid custom floating-point approximation is shown in Fig. 3.6. In this design, $h_\mu(j)$ uses standard 32-bit floating-point number representation, and $W(s|j)$ uses a positive reduced custom floating-point number representation, where the mantissa bit width is the quality configurability knob. This parameter is tuned by the designer to trade-off between QoR and resource utilization, thus, energy consumption.

As the most efficient setup, by completely truncating the mantissa of $W(s|j)$ leads to a slightly

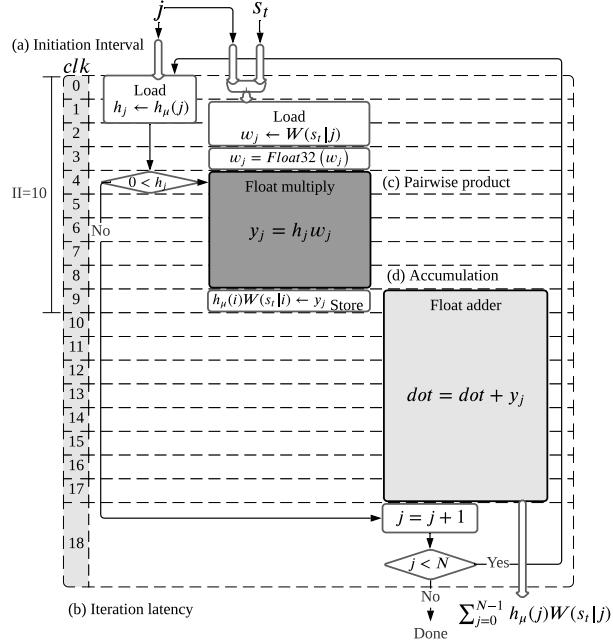

Figure 3.5.: Dot-product hardware module with standard floating-point (IEEE 754) computation, (a) exhibits the initiation interval of 10 clock cycles, (b) presents the iteration latency of 19 clock cycles, (c) shows the pairwise product block in dark-gray, and (d) illustrates the accumulation block in light-gray.

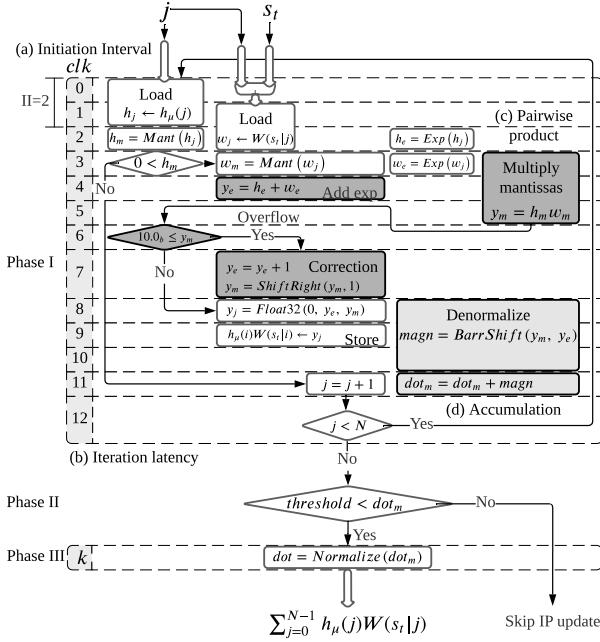

Figure 3.6.: Dot-product hardware module with hybrid custom floating-point approximation, (a) exhibits the initiation interval of 2 clock cycles, (b) presents the iteration latency of 13 clock cycles, (c) shows the pairwise product blocks in dark-gray, and (d) illustrates the accumulation blocks in light-gray.

different hardware architecture using only adders and shifters, which computes the dot-product with hybrid logarithmic approximation. This is shown in **Fig. 3.7**.

Additionally, the exponent bit-width of $W(s|j)$ is a design parameter for efficient resource utilization and it is defined based on the application and deployment needs.

The hybrid custom floating-point and logarithmic approximation designs work in three phases: *Computation*, *Threshold-test*, and *Result normalization*.

- Phase I, *Computation*:

This phase approximates the magnitude of the dot-product in a denormalized representation. This is calculated in two iterative steps over each vector element: *pairwise product* and *accumulation*. *Pairwise product* is executed either in hybrid custom floating-point or hybrid logarithmic approximation described below.

- Pairwise product.

- Hybrid custom floating-point approximation. As shown in **Fig. 3.6(c)** in dark-gray, the pairwise product is approximated by adding exponents and multiplying mantissas of $W(s|i)$ and $h_\mu(i)$. If the mantissa multiplication results in an overflow, then it is corrected by increasing the exponent and shifting the resulting

3. Accelerating Spike-by-Spike Neural Networks

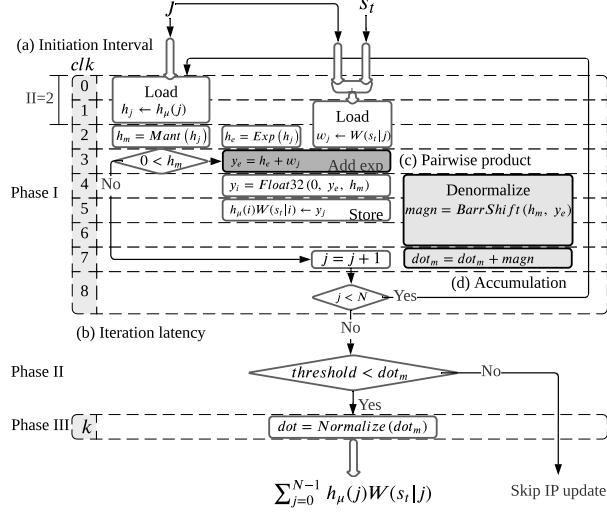

Figure 3.7.: Dot-product hardware module with hybrid logarithmic approximation, (a) exhibits the initiation interval of 2 clock cycles, (b) presents the iteration latency of 9 clock cycles, (c) shows the pairwise product block in dark-gray, and (d) illustrates the accumulation blocks in light-gray.

mantissa by one position to the right. Then, as intermediate result, $h_\mu(j)W(s_t|j)$ is stored for future reuse in the neuron update calculation. In this design, the pairwise product has a latency of 5 clock cycles.

- Hybrid logarithmic approximation. As shown in **Fig. 3.7(c)** in dark-gray, the pairwise product is approximated by adding $W(s|i)$ to the exponent of $h_\mu(i)$, since the values of $W(s|j)$ are represented in the logarithmic domain and $h_\mu(j)$ in standard floating-point. In this design, the pairwise product has a latency of one clock cycle.
- Accumulation. As shown in both **Fig. 3.6(d)** and **Fig. 3.7(d)** in light-gray, first, it is obtained the denormalized representation of $h_\mu(j)W(s_t|j)$ by shifting its mantissa using its exponent as shifting parameter (barrel shifter). Then, this denormalized representation is accumulated to obtain the approximated magnitude of the dot-product.

The process of pairwise product and accumulation iterates over each element of the vectors. The computation latency is given by **Eq. (3.6)** for hybrid custom floating-point, and **Eq. (3.7)** for hybrid logarithmic, where N is the length of the vectors. Both pipelined hardware modules have the same throughput, since both have two clock cycles as initiation

interval.

$$L_{custom} = 2N + 11 \quad (3.6)$$

$$L_{log} = 2N + 7 \quad (3.7)$$

- Phase II, *Threshold-test*:

The accumulated denormalized magnitude is tested to be above of a predefined threshold, it must be above zero, since the dot-product is the denominator in Eq. (2.1). If passing the threshold, then the next phase is executed. Otherwise the rest of update dynamics is skipped. The threshold-test takes one clock cycle.

- Phase III, *Result-normalization*:

In this phase, the dot-product is normalized to obtain the exponent and mantissa in order to convert it to standard floating-point for later use in the neuron update. The normalization is obtained by shifting the approximated dot-product magnitude in a loop until it is in the form of a normalized mantissa where the iteration count represents the exponent of the dot-product. Each iteration takes one clock cycle.

The total latency of the hardware module with hybrid custom floating-point and hybrid logarithmic approximation is the accumulated latency of the three phases.

The proposed architectures with approximation approach exceeds the performance of the design with standard floating-point. This performance enhancement is achieved by decomposing the floating-point computation into an advantageous handling of exponent and mantissa using intermediate accumulation in a denormalized representation and only one final normalization.

3.4. Experimental Results

The proposed architecture is demonstrated on a Xilinx Zynq-7020. This device integrates a dual ARM Cortex-A9 based Processing System (PS) and Programmable Logic (PL) equivalent to Xilinx Artix-7 (FPGA) in a single chip [84]. The Zynq-7020 architecture conveniently maps the custom logic and software in the PL and PS respectively as an embedded system.

In this platform, the proposed hardware architecture is implemented to deploy the SbS network structure shown in 2.1 for handwritten digit classification task for MNIST data set. The SbS model is trained using standard floating-point. Matlab software is used for this SbS network

Table 3.1.: Computation on embedded CPU.

implementation. The resulting synaptic weight matrices are deployed on the embedded system as binary files stored in a micro SD memory card. In the embedded software, the SbS network is built as a sequential model using the API from the SbS embedded software framework [41]. This API allows to configure the computational workload of the neural network, this can be distributed among the hardware processing units and the embedded CPU.

For the evaluation of this approach, it is presented a design exploration by reviewing the computational latency, inference accuracy, resource utilization, and power dissipation. First, the performance of the embedded CPU is taken as benchmark, and then repeat the measurements on hardware processing units with standard floating-point computation. Afterwards, the dot-product architecture is evaluated addressing a design exploration with hybrid custom floating-point approximation, as well as the hybrid logarithmic approximation. Finally, a discussion of results is presented.

3.4.1. Performance Benchmark

Benchmark on Embedded CPU

The performance of the CPU for SbS network inference is examined. In this case, the embedded software builds the SbS network as a sequential model mapping the entire computation to the CPU (ARM Cortex-A9) at 666 MHz and a power dissipation of 1.658 W.

The SbS network computation on the CPU reaches a latency of 34.28 ms per spike with accuracy of 99.3 % correct classification on the 10,000 image test set with 1000 spikes. The latency and schedule of the SbS network computation are displayed in **Tab. 3.1** and **Fig. 3.8**, respectively.

Benchmark on Processing Units with Standard Floating-Point Computation

The system architecture shown in **Fig. 3.9** is implemented to benchmark the computation on hardware PUs with standard floating-point. The embedded software builds the SbS network as

a sequential model and delegates the network computation to the hardware processing units at 200 MHz as clock frequency.

The layers of the neural network with the most neurons are partitioned for asynchronous parallel processing. Since *H2_POOL* and *H3_CONV* are the layers with the most neurons, the computational workload is distributed between two PUs for each one of these layers. The output layer *HY_OUT* is fully processed by the CPU, since it is the layer with fewest neurons. The hardware mapping and the computation schedule of this deployment are displayed in **Tab. 3.2** and **Fig. 3.10**, respectively.

In the computation schedule, the following terms are defined as follows: $t_s(n)$ as the start time

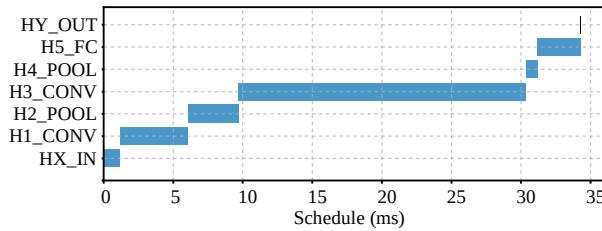

Figure 3.8.: Computation on embedded CPU.

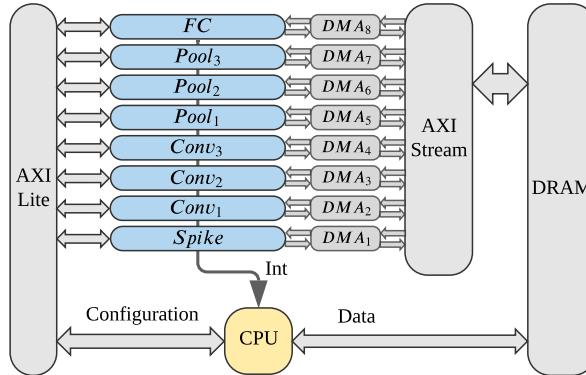

Figure 3.9.: System overview of the top-level architecture with 8 processing units.

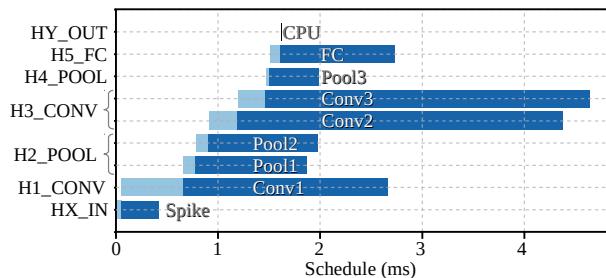

Figure 3.10.: Performance of processing units with standard floating-point (IEEE 754) computation.

3. Accelerating Spike-by-Spike Neural Networks

Table 3.2.: Performance of processing units with standard floating-point (IEEE 754) computation.

Hardware mapping		Computation schedule (ms)			
Layer	PU	t_s	t_{CPU}	t_{PU}	t_f
HX_IN	Spike	0	0.056	0.370	0.426
H1_CONV	Conv1	0.058	0.598	2.002	2.658
H2_POOL	Pool1	0.658	0.126	1.091	1.875
	Pool2	0.785	0.125	1.075	1.985

	Conv3	1.193	0.279	3.176	4.648
H4_POOL	Pool3	1.473	0.037	0.481	1.991
H5_FC	FC	1.512	0.101	1.118	2.731
HY_OUT	CPU	1.615	0.004	0	1.619

for the processing of the neural network layer (as a compute node) $n \in L$ where L represents the set of layers; $t_{CPU}(n)$ as the CPU preprocessing time; $t_{PU}(n)$ as the PU latency; and $t_f(n)$ as the finish time. For data preparation, $t_{CPU}(n)$ is the duration in which the CPU writes a DRAM buffer with \vec{h}_μ (vector of neuron latent variables) of the current processing layer and S_t (input spike matrix) from its preceding layer. This buffer is streamed to the PU via DMA.

The total execution time of the CPU is defined by **Eq. (3.8)**. In a cyclic spiking inference, the execution time of the network computation is the longest path among the processing units including the CPU. This is denoted as the latency of an spike cycle and it is defined by **Eq. (3.10)**. The total execution time of the network computation is the last finish time (t_f) in the schedule defined by **Eq. (3.11)**.

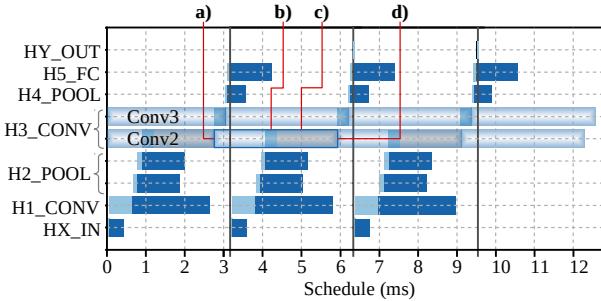

Figure 3.11.: Performance bottleneck of cyclic computation on processing units with standard floating-point (IEEE 754) arithmetic, (a) exhibits the starting of t_{PU} of *Conv2* on a previous computation cycle, (b) presents t_{CPU} of *Conv2* on the current computation cycle, (c) shows the CPU waiting time (in gray color) for *Conv2* as a busy resource (awaiting for *Conv2* interruption), and (d) illustrates the t_f from the previous computation cycle, the starting of t_{PU} on the current computation cycle (*Conv2* interruption on completion, and start current computation cycle).

$$T_{CPU} = \sum_{n \in L} t_{CPU}(n) \quad (3.8)$$

$$T_{PU} = \max_{n \in L} (t_{PU}(n)) \quad (3.9)$$

$$T_{SC} = \begin{cases} T_{PU}, & \text{if } T_{CPU} \leq T_{PU} \\ T_{CPU}, & \text{otherwise} \end{cases} \quad (3.10)$$

$$T_f = \max_{n \in L} (t_f(n)) \quad (3.11)$$

Using standard floating-point requires a high computational cost. As the largest layer, the computational workload of *H3_CONV* is evenly partitioned among two PUs: *Conv2* and *Conv3*. However, in the cyclic schedule, *Conv2* causes the performance bottleneck as shown in **Fig. 3.11**. In this case, the CPU awaits for *Conv2* to finish the computation of the previous cycle in order to start the current computation cycle. In contrast, as the smallest layer, the computational workload of *HY_OUT* is fully processed by the CPU. **Tab. 3.2** and **Fig. 3.10** show 4 μ s as the processing latency of *HY_OUT*. This latency is negligible compared to the overall performance assessment. Accelerating *HY_OUT* would yield a negligible gain. Moreover, assigning a dedicated hardware PU to *HY_OUT* would add unprofitable data transfer and hardware interruption handling overheads.

Applying **Eq. (3.10)**, it is obtained a latency of 3.18 ms per spike cycle. This deployment achieves an accuracy of 98.98% correct classification on the 10,000 image test set with 1000 spikes.

The post-implementation resource utilization and power dissipation are shown in **Tab. 3.3**. Each *Conv* PU instantiates an on-chip stationary weight matrix of 52,000 entries, which is sufficient to store $W \in \mathbb{R}^{5 \times 5 \times 2 \times 32}$ and $W \in \mathbb{R}^{5 \times 5 \times 32 \times 64}$ for *H1_CONV* and *H3_CONV*, respectively. In order to reduce BRAM utilization, we use a custom floating-point representation composed of 4-bit exponent and 4-bit mantissa (bit sign is omitted). Each 8-bit entry is promoted to its standard floating-point representation for the dot-product computation. The method to find the appropriate bit-width parameters for custom floating-point representation is presented in

The implementation of dot-product with standard floating-point arithmetic (IEEE 754) utilizes proprietary Xilinx multiplier and adder floating-point operator cores. Vivado HLS implements floating-point arithmetic operations by mapping them onto Xilinx LogiCORE IP cores, these floating-point operator cores are instantiated in the resultant Register-Transfer Level (RTL)[85]. In this case, the implementation of the dot-product with the standard floating-point computation reuses the multiplier and adder cores already instantiated and used in other computation sections of *Conv* and *FC* processing units. The post-implementation resource utilization and power dissipation of the floating-point operator cores are shown in **Tab. 4.3**.

Benchmark on Noise Tolerance Plot

The purpose of the proposed noise tolerance plot is to serve as an intuitive visual model used to provide insights into accuracy degradation under approximate processing effects. This plot reveals inherent error resilience, and hence, approximation resilience. As an application-specific quality metric, this plot offers an effective method to estimate the overall quality degradation of the SbS network under different approximate processing effects, since both approximations and noise have qualitatively the same effect [66].

In order to experimentally obtain the noise tolerance plot, the inference accuracy of the neural network with increasing number of spikes is measured. The measurements are retaken with uniformly distributed noise applied on the input. The levels of the noise amplitude are gradually ascended until accuracy degradation is detected. **Fig. 3.12** demonstrates this method using 100 input samples.

As benchmark, the tolerance plot in **Fig. 3.12** reveals accuracy degradation having 50% noise and convergence with 400 spikes. In this case, the given SbS network with precise processing demonstrates its inherent error resilience, hence, the resilience for approximate processing.

3.4.2. Design Exploration with Hybrid Custom Floating-Point and Logarithmic Approximation

In this section, it is presented a design exploration to evaluate the proposed approach for SbS neural network inference using hybrid custom floating-point and logarithmic approximation.

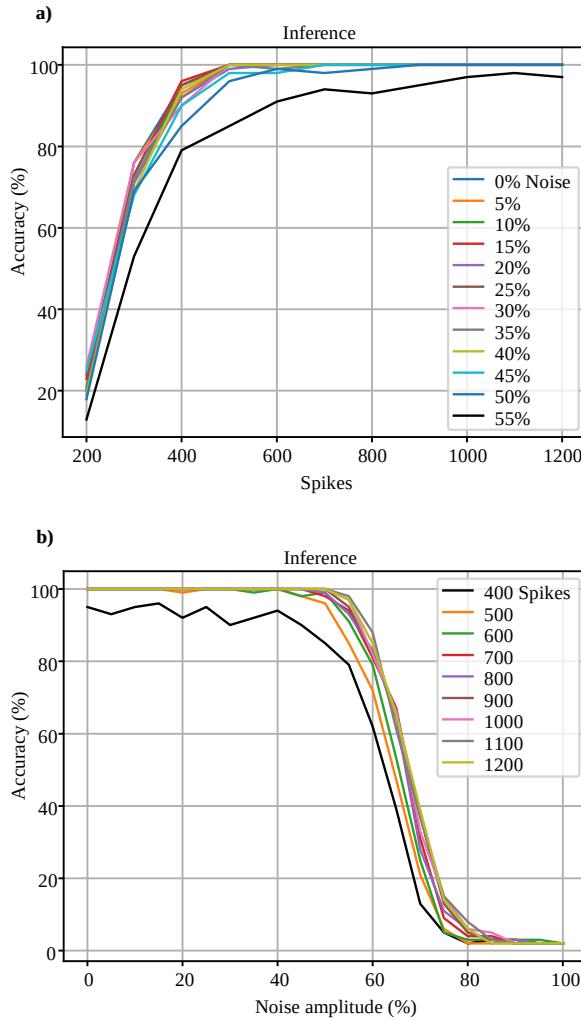

Figure 3.12.: Noise tolerance on hardware PU with standard floating-point (IEEE 754) computation (benchmark/reference), (a) exhibits accuracy degradation applying 50% of noise amplitude, and (b) illustrates convergence of inference with 400 spikes.

First, the synaptic weight matrix of each layer is examined in order to determine the minimum requirements for numeric representation and memory storage. Second, the proposed dot-product architecture is implemented using the minimal floating-point and logarithmic representation as design parameters. Finally, it is presented an evaluation of the overall performance, inference accuracy, resource utilization, and power dissipation.

Parameters for Numeric Representation of Synaptic Weight Matrix

The parameters for numerical representation of the synaptic weight matrices is obtained from their \log_2 -histograms presented in **Fig. 3.13**. These histograms show the distribution of synaptic weight values in each matrix. The histograms show that the minimum integer exponent value is -13 . Hence, applying **Eq. (3.2)** and **Eq. (3.3)** to the given SbS network, results $E_{\min} = -13$ and $N_E = 4$, respectively. Therefore, 4-bits are used for the absolute binary representation of the exponents.

For quality configurability, the mantissa bit-width is a knob parameter that is tuned by the designer. This procedure leverages the builtin error-tolerance of neural networks and performs a trade-off between resource utilization and QoR. In the following subsection, a case study is presented with 1-bit mantissa. This corresponds to the custom floating-point approximation.

Design Exploration for Dot-product with Hybrid Custom Floating-Point Approximation

For this design exploration, a custom floating-point representation is composed of 4-bit exponent and 1-bit mantissa. This format is used for the synaptic weight vector on the proposed dot-product architecture. Each *Conv* PU instantiates an on-chip stationary weight matrix for 52,000 entries of 5-bit. The available memory size is large enough to store $W \in \mathbb{R}^{5 \times 5 \times 2 \times 32}$ and $W \in \mathbb{R}^{5 \times 5 \times 32 \times 64}$ for *H1_CONV* and *H3_CONV*, respectively. The same dot-product architecture is implemented in the processing unit of the fully connected layer (*FC*). However, due to lack of BRAM resources, this PU can not instantiate on-chip stationary synaptic weight matrix. Instead, *FC* receives the $\vec{W}(s_t)$ (weight vectors) during operation as well as \vec{h}_μ and S_t . The hardware mapping and the computation schedule of this implementation are displayed in **Tab. 3.6** and **Fig. 3.14**.

As shown in the computation schedule in **Tab. 3.6** and **Fig. 3.14**, this implementation presents a maximum hardware PU latency of 1.30 ms according to **Eq. (3.9)**, and CPU latency of 1.67 ms. Therefore, applying **Eq. (3.10)**, the total latency is 1.67 ms per spike cycle as shown in **Fig. 3.14**. In this case, the cyclic bottleneck in each SbS spike is in the CPU performance.

This configuration achieves an accuracy of 98.97% correct classification on the 10,000 image test set with 1000 spikes. This indicates an accuracy degradation of 0.33%. To monitoring

output quality, the noise tolerance plot in **Fig. 3.15** reveals accuracy degradation for noise higher than 50% on the input images, and convergence of inference with 400 spikes. Thus, the particular SbS network implementation under approximate processing effects demonstrates a minimal impact on the overall accuracy. This reveals an inherent error resilience, and hence, remaining approximation budget.

The post-implementation resource utilization and power dissipation of this design are shown in **Tab. 3.5**.

Table 3.5.: Resource utilization and power dissipation of processing units with hybrid custom floating-point approximation.

Design Exploration for Dot-Product whit Hybrid Logarithmic Approximation

For this design, 4-bit integer exponent are used for logarithmic representation of the synaptic weight matrix. Each *Conv* processing unit implements the proposed dot-product architecture including an on-chip stationary weight matrix for 52,000 entries of 4-bit integer each one to store $W \in \mathbb{N}^{5 \times 5 \times 2 \times 32}$ and $W \in \mathbb{N}^{5 \times 5 \times 32 \times 64}$ for *H1_CONV* and *H3_CONV*, respectively. The same dot-product architecture is implemented in the *FC* processing unit without stationary synaptic weight matrix. The hardware assignment and the computation schedule of this implementation

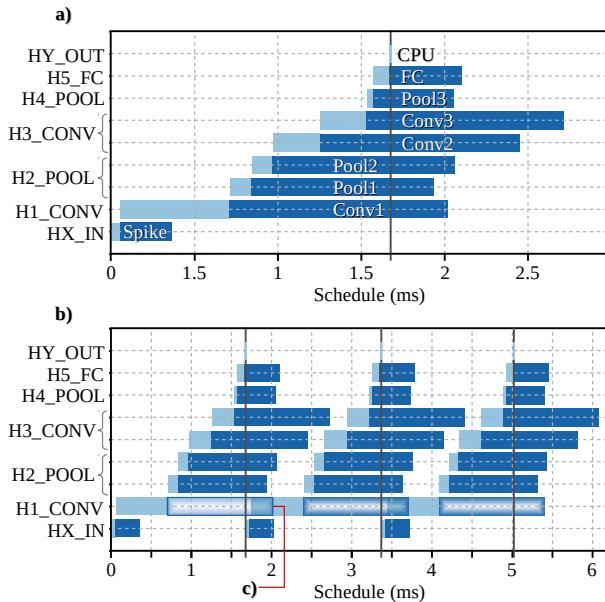

Figure 3.14.: Performance on processing units with hybrid custom floating-point approximation, (a) exhibits computation schedule, (b) presents cyclic computation schedule, and (c) shows the performance of *Conv2* from a previous computation cycle during the preprocessing of *H1_CONV* on the current computation cycle without bottleneck.

are displayed in **Tab.** 3.7 and **Fig.** 3.16.

As shown in the computation schedule in **Tab.** 3.7 and **Fig.** 3.16, this implementation presents a maximum hardware PU latency of 1.27 ms (according to **Eq.** (3.9)), and CPU latency of 1.67 ms. Therefore, applying **Eq.** (3.10), gives 1.67 ms as latency per spike cycle as shown in **Fig.** 3.16. In this case, the cyclic bottleneck is in the CPU performance.

This quality configuration achieves an accuracy of 98.84% correct classification on the 10,000 image test set with 1000 spikes. This indicates an accuracy degradation of 0.46%. To monitor output quality, the noise tolerance plot in **Fig.** 3.17 reveals accuracy degradation having 40% noise on the input images, and convergence of inference with 600 spikes. The particular SbS

3.4.3. Results and Discussion

As benchmark, the SbS network inference on embedded CPU using standard 32-bit floating-point achieves an accuracy of 99.3% with a latency of $T_{SC} = 34.28ms$. As a second reference point, the network simulation on hardware processing units with standard floating-point achieves an accuracy of 98.98% with a latency $T_{SC} = 3.18ms$. As result, this design get $10.7\times$ latency enhancement and an accuracy degradation of 0.32%. The tolerance plot in **Fig. 3.12** reveals accuracy degradation having 50% noise on the input images, and convergence of inference with 400 spikes. In this case, the SbS network deployment with precise computing proves extraordinary inherent error resilience, and hence, this represents a great potential for approximate

processing.

As a demonstration of the proposed dot-product architecture, the SbS network inference on hardware PUs with synaptic representation using 5-bit custom floating-point (4-bit exponent, 1-bit mantissa) and 4-bit logarithmic (4-bit exponent) achieve 20.5 \times latency enhancement and accuracy of 98.97% and 98.84%, respectively. This results in accuracy degradation of 0.33% and 0.46%, respectively. To monitor output quality, the noise tolerance plot in **Fig. 3.15** and **Fig. 3.17** reveal accuracy degradation when having 50% and 40% noise on the input images, and convergence of inference with 400 and 600 spikes, respectively. Therefore, the design exploration under the proposed approximate computing approach indicates sufficient inherent error resilience for further or more aggressive approximation approaches.

Regarding resource utilization and power dissipation with the proposed approach, *Conv* processing units have a 43.24% reduction of BRAM, and 12.35% of improvement in energy efficiency over the standard floating-point implementation. However, the proposed approach does not reuse the available floating-point operator cores instantiated from other computational sections (see **Tab. 4.3**). Therefore, the logic required for the dot-product must be implemented, which is reflected as additional utilization of LUT and FF resources. The experimental results of the design exploration are summarized in **Tab. 3.9**. The platform implementations are summarized in **Tab. 3.10**, and their power dissipation breakdowns are presented in **Fig. 3.18**.

3.5. Conclusions

In this work, we accelerate SbS neural networks with a dot-product functional unit based on approximate computing that combinesthe advantages of custom floating-point and logarithmic

representations. This approach reduces computational latency, memory footprint, and power dissipation while preserving classification accuracy. For output quality monitoring, we applied noise tolerance plots as an intuitive visual measure to provide insights into the accuracy degradation of SbS networks under different approximate processing effects. This plot reveals inherent error resilience, hence, the possibilities for approximate processing.

The proposed approach is demonstrated with a design exploration flow on a Xilinx Zynq-7020 with a deployment of SbS network for MNIST classification task. This implementation achieves up to 20.5× latency enhancement, 8× weight memory footprint reduction, and 12.35% of energy efficiency improvement over the standard floating-point hardware implementation, this deployment incurs in less than 0.5% of accuracy degradation. Furthermore, with noise amplitude of 50% added on the input images, the SbS network presents an accuracy degradation of less than 5%. To monitor the inference quality, the resulting noise tolerance plots demonstrate a sufficient QoR for minimal impact on the overall accuracy of the neural network under the effects of this approximation technique. These results suggest available room for further or more aggressive

approximate processing approaches.

In summary, based on the relaxed need for fully accurate or deterministic computation of neural networks, approximate computing techniques allow substantial enhancement in processing efficiency with moderated accuracy degradation.

4.1. Introduction

There is a growing demand for sensor analytics based on ML algorithms. Industry 4.0 and smart city infrastructure leverage AI solutions to increase productivity and adaptability [86].

4. Accelerating Convolutional Neural Networks

These solutions are powered by advances in ML, compute engines, and big data. Therefore, enhancement of these should be considered for research, as they are the machinery of the future.

CNNs represent the essential building blocks in 2D pattern analytics. Sensor-based applications such as mechanical fault diagnosis [42, 43], structural health monitoring [44], human activity recognition [45], hazardous gas detection [46] have been powered by CNN models in industry and academia. CNN-based models, as one of the main types of ANN, have been widely used in sensor analytics with automatic learning from sensor data [87, 88, 89, 90]. In this context, CNN models are applied for automatic feature learning, usually, from 1D time series as well as for 2D time-frequency spectrograms. CNN models provide advantages such as local dependency, scale invariance, and noise resilience in analytics [25]. However, CNN models are computationally intensive and power-hungry. This is particularly challenging for low-power embedded applications, such as in the IoT field.

For ML inference, dedicated hardware architectures are typically used to enhance compute performance and power efficiency. In terms of computational throughput, Graphics Processing Units (GPUs) offer the highest performance; in terms of power efficiency, ASIC and FPGA solutions are more energy efficient [91]. As a result, numerous commercial ASIC and FPGA accelerators have been proposed, targeting both HPC for data-centers and embedded systems applications.

However, most FPGA accelerators have been implemented to target mid- to high-range FPGAs for computationally intensive CNN models such as AlexNet, VGG-16, and ResNet-18. The main drawbacks of these implementations are power supply demands, physical dimensions, heat sink requirements, air cooling, and high price. In some cases, these implementations are not feasible for ubiquitous low-power/resource-constrained applications.

To reduce hardware there are two types of research [92]: the first one is deep compression including weight pruning, weight quantization, and compression storage [14, 93]; the second type of research corresponds to a more efficient data representation, also known as custom quantization for dedicated hardware implementation. In this group, hardware implementations with customized 8-bit floating-point computation have been proposed [94, 92, 95]. However, these architectures are inadequate for embedded applications, the target devices are high-end FPGAs and PCIe devices.

Reducing the compute hardware with more aggressive quantization such as binary [13], ternary [47], and mixed precision (2-bit activations and ternary weights) [48] typically incur significant accuracy degradation for very low precisions, especially for complex problems that require precision [49].

In this chapter, it is presented the Hybrid-Float6 quantization and its dedicated hardware design. In this approach, feature maps are represented by a standard FP number representation

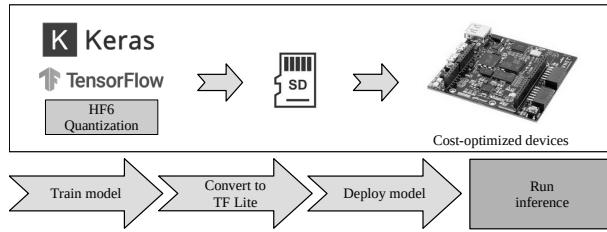

Figure 4.1.: The workflow of our approach on embedded FPGAs.

and trainable parameters by 6-bit FP. To preserve accuracy, a QAT method is proposed. For ML compatibility/portability, the 6-bit FP can be wrapped into the standard FP number representation. It is presented a parameterized tensor processor implementing a pipelined vector dot-product with HF6. The proposed hardware extracts the 6-bit representation automatically from the standard FP format and performs the computation. The 6-bit FP representation uses 4-bit exponent and 1-bit mantissa. This approach enables optimizations in MAC design by reducing the mantissa multiplication to a multiplexer-adder operation. Moreover, the intrinsic error tolerance of ANN is leveraged to further reduce the hardware design with approximation. This approach reduces latency, resource utilization, and power dissipation. The embedded hardware/software architecture is integrated with TensorFlow Lite using delegate interface to accelerate *Conv2D* tensor operations. We evaluate the applicability of our approach with a CNN-regression model and hardware design exploration for sensor analytics of SHM for anomaly localization. The embedded hardware/software framework is demonstrated on XC7Z007S, this is the smallest and most inexpensive Zynq SoC device, see **Fig. 4.1**. To the best of my knowledge, this is the first research addressing 6-bit floating-point quantization on CNN models and its dedicated hardware design.

The main contributions presented in this chapter are as follows:

1. The Hybrid-Float6 quantization and its dedicated hardware design. It is proposed an optimized hardware MAC by reducing the mantissa multiplication to a multiplexer-adder operation. The intrinsic error tolerance of ANN is exploited to further reduce the hardware design with approximation. To preserve model accuracy, it is presented a quantization-aware training method, which provides regularization effects.
2. A custom hardware/software co-design framework for low-power analytics on resource-constrained embedded FPGA. TensorFlow Lite micro is integrated in this framework.
3. A customizable tensor processor as a dedicated hardware for HF6. This design computes *Conv2D* tensor operations employing a pipelined vector dot-product with parametrized on-chip memory utilization. For exploration purposes, the compute engine can be synthesized

4. Accelerating Convolutional Neural Networks

with the proposed HF6 hardware or with Xilinx LogiCORE IPs (for standard floating-point).

4. The potential of this approach is demonstrated with a CNN-regression model for anomaly localization in SHM based on AE. A hardware design exploration is presented evaluating inference accuracy, compute performance, hardware resource utilization, and energy consumption.

This work is available to the community as an open-source project at
<https://github.com/YaribNevarez/tensorflow-lite-fpga-delegate.git>.

4.2. Related work

In the literature we find plenty of hardware architectures for CNN accelerators implemented in FPGA. Most of the research work implements fixed-point quantization, and very limited research focuses on FP. Moreover, to the best of my knowledge, there is no research work related to FP inference for low-power embedded applications.

4.2.1. Hybrid Custom Floating-Point

In [96], Liangzhen Lai et al. proposed a mixed data representation with floating-point for weights and fixed-point for activations. This work demonstrated on SqueezeNet, AlexNet, GoogLeNet, and VGG-16 that 8-bit floating-point quantization (4-bit exponent and 3-bit mantissa) results in constant negligible accuracy degradation. Similarly, in [97], Sean O. Settle et al. presented an 8-bit FP quantization scheme, which needs an extra inference batch to compensate for quantization errors. However, [96] and [97] did not present a dedicated hardware architecture.

In [95], Xiaocong Lian et al. proposed a hardware accelerator with optimized block floating-point (BFP). In this design the activations and weights are represented by 16-bit and 8-bit FP formats, respectively. This design is demonstrated on Xilinx VC709 evaluation board. This implementation achieves throughput and power efficiency of 760.83 GOP/s and 82.88 GOP/s/W, respectively. However, this design is not suitable for low-power resource-constrained embedded FPGAs.

4.2.2. Low-Precision Floating-Point

In [94], Chunsheng Mei et al. presented a hardware accelerator for VGG16 model using half-precision FP (16-bit). This design is demonstrated on Xilinx Virtex-7 (XC7VX690T) with PCIe

interface. This implementation achieves throughput and power efficiency of 202.8 GFLOP/s and 18.72 GFLOP/s/W, respectively. In [92], Chen Wu et al. proposed a low-precision (8-bit) floating-point (LPFP) quantization method for FPGA-based acceleration. This design is demonstrated on Xilinx Kintex 7 and Ultrascale/Ultrascale+. This implementation achieves throughput and power efficiency of 1086.8 GOP/s and 115.4 GOP/s/W, respectively.

4.2.3. Low-Power

Two research papers have been reported hardware accelerators targeting XC7Z007S. This is the smallest and most inexpensive device from Zynq-7000 SoC family. In [98], Paolo Meloni et al. presented a CNN inference accelerator for compact and cost-optimized devices. This implementation uses fixed-point to process light-weight CNN architectures with a power efficiency between 2.49 to 2.98 GOPS/s/W. In [99], Chang Gao et al. presented EdgeDRNN, a Recurrent Neural Network (RNN) accelerator for edge inference. This implementation adopts the SNN inspired delta network algorithm to exploit temporal sparsity in RNNs.

4.3. System Design

The system design is a hardware/software co-design framework for low-power ML analytics. This architecture allows design exploration for dedicated hardware in embedded systems. For ML compatibility, the proposed framework integrates TensorFlow Lite micro.

4.3.1. Base embedded system architecture

The embedded system architecture consists of a cooperative hardware-software platform. See **Fig. 4.2**. The embedded CPU delegates low-level compute-bound tensor operations to the TPs. The TPs employ AXI-Lite interface for configuration and AXI-Stream interfaces via DMA for data movement from off-chip memory. Each TP and DMA pair asserts interrupt flags once its compute job/transaction completes. Interrupt events are handled by the embedded CPU to use the results and to start a new compute job/transaction. The hardware architecture can vary its resource utilization by customizing the TPs prior to the hardware synthesis.

4.3.2. Tensor processor

The TP is a dedicated hardware module to compute tensor operations. This implements high performance communication with AXI-Stream, direct CPU communication with AXI-Lite, and

4. Accelerating Convolutional Neural Networks

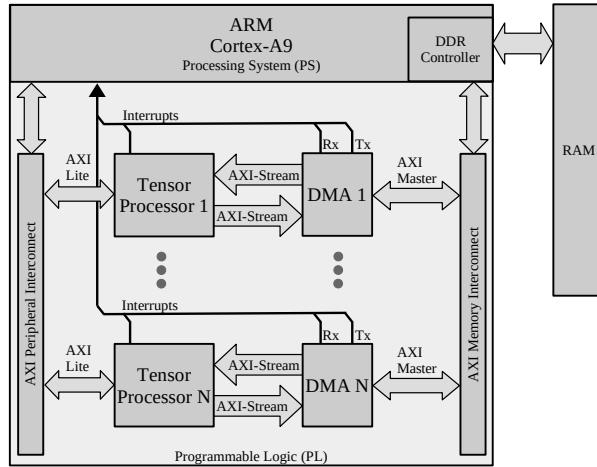

Figure 4.2.: Base embedded system architecture.

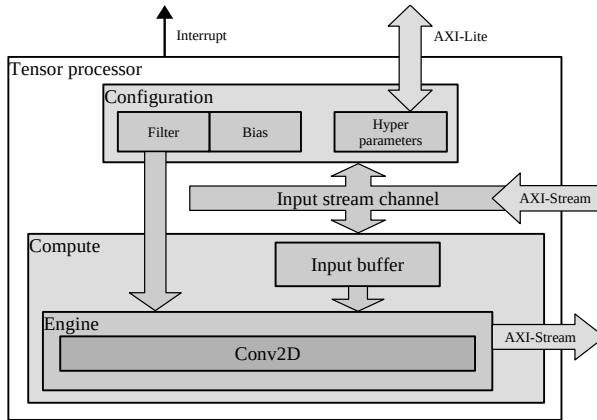

Figure 4.3.: High level hardware architecture of the proposed tensor processor.

on-chip storage utilizing BRAM. This hardware architecture is implemented with HLS. The tensor operations are implemented based on the C++ TensorFlow Lite micro kernels. See **Fig. 4.3.** This research focuses on the *Conv2D* tensor operation that computes 2D convolution layers.

Modes of operation

The TP has two modes of operation: *configuration* and *execution*.

- In *configuration* mode, the TP receives the hyperparameters of the tensor operation: stride, dilation, padding, offset, activation, depth-multiplier, input shape, filter shape, bias shape, and output shape. Afterwards, in the same data stream, the TP receives filter and bias tensors. These are locally stored in BRAM for data re-usage. The filter and bias tensors

are transferred using standard FP format wrapping the 6-bit FP representation, which is extracted by the TP for local on-chip storage.

- In *execution* mode, the TP executes the tensor operation according to the hyperparameters given in the configuration mode. During execution, the input and output tensors are moved via DMA.

Dot-product with hybrid floating-point

We implement the floating-point computation adopting the dot-product with hybrid custom floating-point [50]. The hardware dot-product is illustrated in **Fig. 4.4** and **Fig. 4.5(a)**. This design instantiates a HF6 MAC with an internal accumulator register of 64-bit fixed-point with 23-bit fraction. During operation, the feature map and filter values are extracted from on-chip memory (BRAM). Both values have to be different than zero to enable the MAC operation. The result is biased by accumulating a denormalized bias value. Since the bias is stored with 6-bit FP, its fractional part has to be aligned with the 23-bit fraction of the accumulator, see **Fig. 4.5(b)**. The ReLu activation is applied to the accumulator and its result is normalized to convert it to IEEE 754 standard FP, see **Fig. 4.5(c)**.

Rather than a parallelized hardware structure, this approach is a pipelined hardware design suitable for resource-limited devices. The latency in clock cycles of this hardware module is defined by **Eq. (4.1)**, where N is the length for the vector dot-product. This latency equation is obtained from the general pipelined hardware latency formula: $L = (N - 1)II + IL$, where II is the initiation interval, and IL is the iteration latency. Both II and IL are obtained from the HLS results. Both the exponent and mantissa bit widths of the filter and bias are set to 4-bit exponent and 1-bit mantissa (E4M1), which corresponds to float6 quantization.

$$L_{hf} = N + 7 \quad (4.1)$$

Multiply-Accumulate

The multiply-accumulate operation calculates the product of two numbers and adds the result to an accumulator. In FP arithmetics, the area of a hardware multiplier scales with the bit size of the mantissas. In the case of HF6, the 6-bit FP representation allows a reduced hardware multiplicator for mantissas. The 1-bit mantissa enables optimized MAC implementations by reducing the mantissa multiplication to a multiplexed addition, see **Fig. 4.6**. This MAC produces

4. Accelerating Convolutional Neural Networks

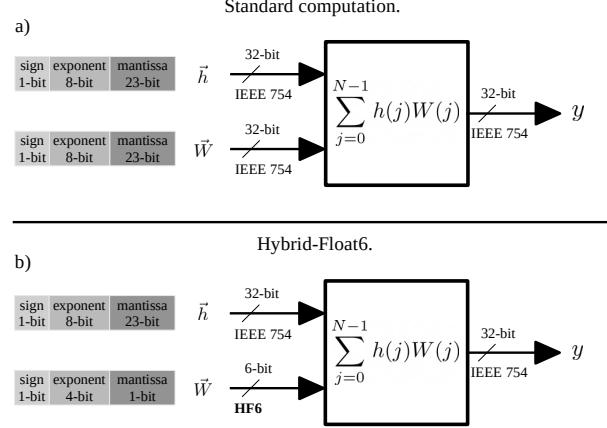

Figure 4.4.: Dot-product hardware module with (a) standard floating-point and (b) Hybrid-Float6.

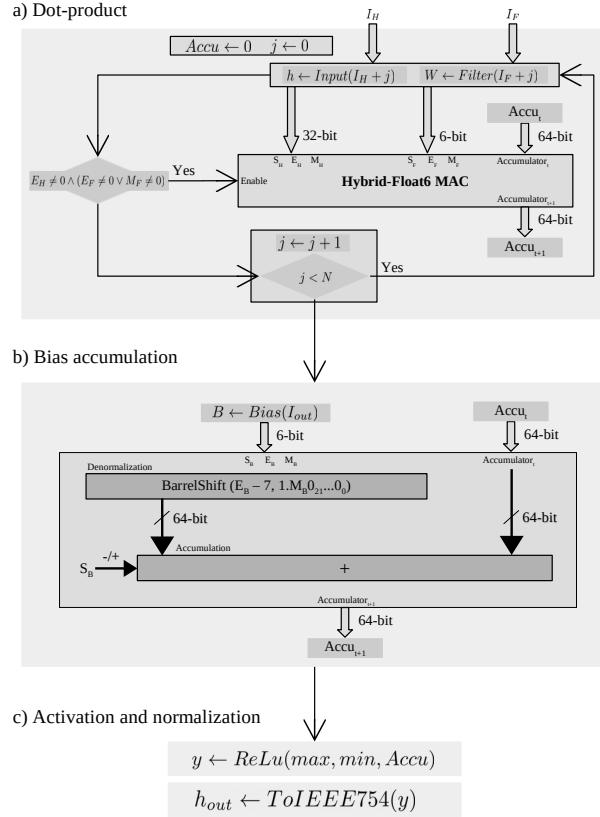

Figure 4.5.: (a) Dot-product hardware module with Hybrid-Float6 MAC, (b) bias accumulation, (c) activation and normalization to IEEE754.

denormalized results, which are accumulated in a fixed-point accumulator. This approach reduces latency, energy consumption, and hardware area/resource utilization.

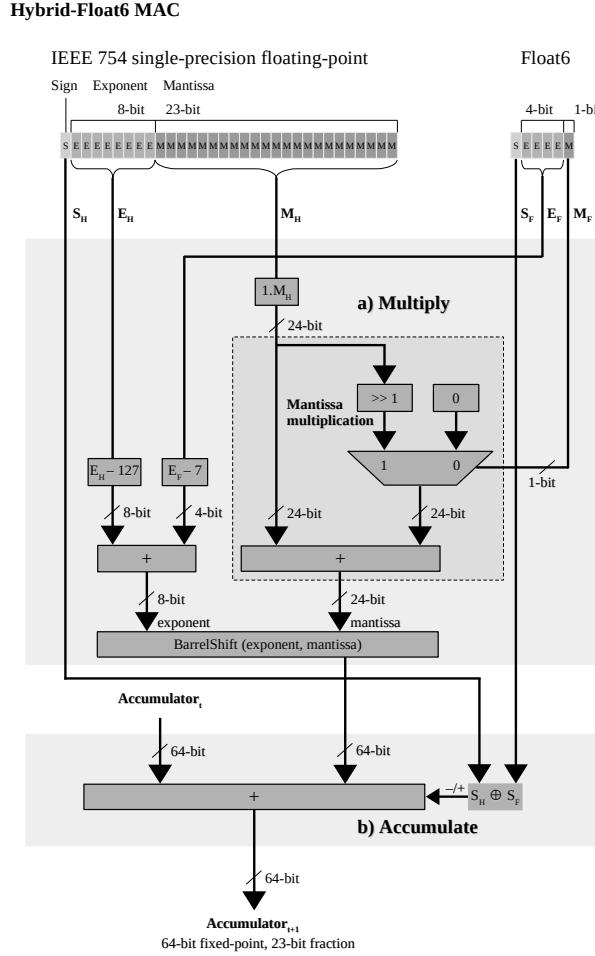

Figure 4.6.: Hybrid-Float6 multiply-accumulate hardware design.

Special cases, such as Infinity and NaN, are not considered in this design for simplicity, since they are not expected for CNN inference. For the subnormal case, the element-wise multiplication is disabled when having a zero entry and approximated when having subnormal mantissa. The feature map values are considered zero when the exponent is zero ($E_H = 0$). The filter values are considered zero when both exponent and mantissa are zero ($E_F = 0 \wedge M_F = 0$). See **Fig. 4.5(a)**. In the 6-bit FP, the 1-bit mantissa has one subnormal case, which is handled as a normalized case. This exploits the intrinsic error tolerance to reduce the hardware design.

The approximation error is defined by the difference between **Eq. (2.3)** and **Eq. (2.5)** when $E = 0$ and $M = 2^{-1}$. The result defines the error as $e = 2^{-B-1}$. Then, from **Eq. (2.4)** with $E_{size} = 4$, gives $B = 7$. Hence, $e = 3.9e-3$. This error is produced when having the subnormal case $E = 0$ and $M = 2^{-1}$, which corresponds to the value $\pm 7.8e-3$ deviated to $\pm 1.17e-2$. This approximation leverages the intrinsic error tolerance of CNN to reduce hardware resource utilization and energy consumption [25].

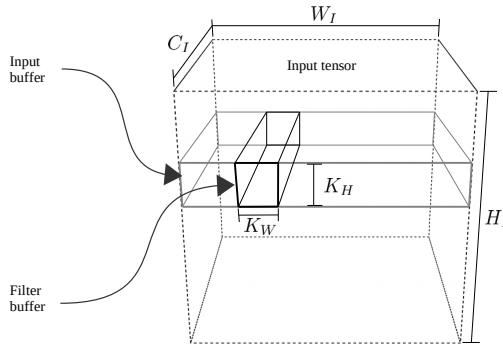

Figure 4.7.: Design parameters for on-chip memory buffers on the TP.

On-chip memory utilization

The total on-chip memory utilization on the TP is defined by **Eq. (4.2)**, where TP_B and V_M represent the tensor buffers required for *Conv* operation and local registers required for the logic, respectively. **Eq. (4.3)** defines the tensor buffers, where $Input_M$ is the *input buffer*, $Filter_M$ is the *filter buffer*, $Bias_M$ is the *bias buffer*. These on-chip memory buffers are defined in bits. **Fig. 4.7** illustrates the convolution operation utilizing the on-chip memory buffers.

$$TP_M = TP_B + V_M \quad (4.2)$$

$$TP_B = Input_M + Filter_M + Bias_M \quad (4.3)$$

The memory utilization of *input buffer* is defined by **Eq. (4.4)**, where K_H is the height of the convolution kernel, W_I is the width of the input tensor (input feature maps), C_I is the number of input channels, and $BitSize_I$ is the bit size representation used by the input tensor.

$$Input_M = K_H W_I C_I BitSize_I \quad (4.4)$$

The memory utilization of *filter buffer* is defined by **Eq. (4.5)**, where K_W and K_H are the width and height of the convolution kernel, respectively; C_I and C_O are the number of input and output channels, respectively; and $BitSize_F$ is the bit size representation used by filter values.

$$Filter_M = C_I K_W K_H C_O BitSize_F \quad (4.5)$$

The memory utilization of *bias buffer* is defined by **Eq. (4.6)**, where C_O is the number of

output channels, and $BitSize_B$ is the bit size representation used by bias values.

$$Bias_M = C_O BitSize_B \quad (4.6)$$

As a design trade-off, Eq. (4.7) defines the capacity of output channels based on given design parameters. The total on-chip memory TP_M determines the TP storage capacity.

$$C_O = \frac{TP_M - V_M - K_H W_I C_I BitSize_I}{C_I K_W K_H BitSize_F + BitSize_B} \quad (4.7)$$

The floating-point formats implemented in the TP are defined by $BitSize_F$, $BitSize_B$ and $BitSize_I$. The HF6 defines 6-bit for $BitSize_F$ and $BitSize_B$, and 32-bit for $BitSize_I$. These are design parameters defined before hardware synthesis. This allows fine control of BRAM utilization, which is suitable for resource-limited devices.

4.3.3. Training Method

The training method consists of two separate stages: (1) training with iterative early stop and (2) quantization-aware training.

Training with Iterative Early Stop

To achieve better performance on CNN-regression models, it implemented a training procedure with iterative early stop cycle. This allows to reach better local minima. This process consists of four steps:

1. A model is obtained with an initial training with standard early stop monitoring.
2. The model is iteratively re-trained with standard early stop. This process iteratively restarts the moving averages of the optimizer to search for better local minima.
3. In case of a better local minimum, the model is saved and used as a base for subsequent search iterations, otherwise it is a discarded search.
4. The cyclic process stops automatically with a given number of searches without a better local minimum, this is denoted as stop patience. This allows to set a maximum number of unsuccessful search trials before the stop.

This method is described in **Algorithm ??**.

Quantization-Aware Training

The QAT method is integrated into the training process, this operates as a callback on each mini-batch update. The quantization is applied on the trainable parameters of convolution layers. This method is implemented on the ML framework (TensorFlow/Keras), see **Algorithm ??**.

The quantization method uses rounding strategy to reduce the FP representation. This maps the full precision FP values to the closest representable 6-bit FP values, see **Algorithm ??**. This method quantizes the filter and bias tensors of the convolution layers. The exponent bit size plays a more predominant influence on the model accuracy than the mantissa bit size. In [96], Lai et al. demonstrated that 4-bit exponent and X-bit mantissa is adequate and consistent across different networks (SqueezeNet, AlexNet, GoogLeNet, VGG-16). In this research, the FP representation with 4-bit exponent and 1-bit mantissa is investigated.

4.3.4. Embedded software architecture

The software architecture is a layered object-oriented application framework written in C++, see **Fig. 4.8** and **Fig. 4.9**. Description of the software layers is as follows:

- *Application:* As the highest level of abstraction, this software layer implements the analytics application, this invokes the ML library.

- *Machine learning library*: This software layer offers a comprehensive high level API for ML inference. This layer consist of TensorFlow Lite micro, this is modified to implement the delegate software interfaces for the proposed hardware accelerator.
- *Hardware abstraction layer*: This layer consist of the hardware drivers used in the TFLite delegate interfaces. This software layer handles initialization and runtime operation of the TP and DMA.

4.4. Experimental Results

This section presents experimental results using a low-power/low-cost sensor analytics application. A CNN-regression model is proposed to predict x- y- coordinates of acoustic emissions based on piezoelectric vibrations. Quantitative and qualitative aspects of the analytics are compared using floating-point 32-bit, fixed-point 8-bit, Hybrid-Logarithmic 6-bit, and Hybrid-Float6.

To demonstrate the proposed concept, the CNN model is deployed in the smallest Zynq SoC FPGA device for low-power inference. The performance of the TP synthesized with standard FP (using Xilinx LogiCORE IPs) and Hybrid-Float6 design.

4.4.1. Sensor Analytics Application

The analytics model is designed to predict x- y- coordinates of acoustic emissions on a metal plate. The metal plate is in the presence of noise disturbance to simulate realistic conditions. This subsection presents the structure for experimental setup, data sets, and the CNN-regression model.

Experimental Setup

The experiment uses eight piezoelectric sensors (Vallen Systeme VS900) attached with magnetic holders on a metal plate ($90\text{ cm} \times 86.6\text{ cm} \times 0.3\text{ cm}$). The VS900 devices can operate either in active or passive mode. Six VS900 are used in passive mode as acoustic sensors and two in active mode to produce acoustic emissions. These acoustic emissions simulate anomalies on x- y- coordinates as well as the noise disturbance on the system. See **Fig. 4.10(a)**. To create data sets, the samples of acoustic emissions are labeled with their coordinates.

Data Sets

The data sets are recorded applying pulses on the metal plate, the x- y- coordinates of these pulses are used as labels. The pulses for training and validation data sets are shown in **Fig. 4.10(b)** and **Fig. 4.10(c)**, respectively. The pulses for training and validation data sets are mutually exclusive, this exclusion is represented by the cross symbols in **Fig. 4.10(c)**. This creates a grid layout used to collect samples for the data sets. This grid is 10×10 divisions, these are on the metal plate area ($90 \text{ cm} \times 86.6 \text{ cm}$). This grid does not consider the four corners as they are used for magnetic holders.

In order to create reproducible acoustic emissions, this demonstration uses 9-cycle sine pulse in a Hanning window with central frequency f_c (narrow-banded in the frequency domain). This experiment assumes guided Lamb waves based on the plate structure. The narrow-band behavior also reduces the dispersion of the acoustic emission waves [100]. The waveform can be expressed as a function of time t as follows:

$$x_{\text{pulse}}(t) = \frac{1}{2} \left(1 - \cos \frac{f_c t}{5} \right) A_0 \sin f_c t. \quad (4.8)$$

To generate the data sets, slightly different pulse amplitudes and frequencies for excitation are used. The pulse frequency f_c is varied in 1 kHz steps between 300 kHz and 349 kHz and the amplitude A_0 is varied in 0.1 V steps between 2.6 V and 3.5 V. This produces 500 different pulses for each of the excitation points.

The signals for labeled pulses and noise disturbance are generated by Arbitrary Waveform Generators (AWGs). The sensor signals are recorded via a Vallen AMSY-6 measurement system with a resolution of 18 bits and a sampling rate of $f_s = 10 \text{ MHz}$. The disturbance signal is gaussian noise with amplitudes between 0-3 V. This noise is applied via the piezoelectric device N at $x = 0.227 \text{ m}$ and $y = 0.828 \text{ m}$, see **Fig. 4.10(a)**.

To obtain frequency components, the sampled pulses are converted into the frequency-time domain using the Short-Time Fourier Transform (STFT). This is calculated as follows [101]:

$$\mathcal{F}_{m,k}^{\gamma} = \sum_{n=0}^{N-1} x[n] \cdot \gamma^*[n - m\Delta M] \cdot e^{-j\frac{2\pi kn}{N}} \quad (4.9)$$

Here $x[n]$ describes a discrete-time signal and $\gamma^*[n - m\Delta M] \cdot e^{-j\frac{2\pi kn}{N}}$ the time- and frequency-shifted window function inside the considered interval $[0, N-1]$. ΔM describes the time shift and N the transformation window. Since only discrete frequencies and time points are considered, $m = 0, 1, \dots, M-1$ is valid. For pictorial representation, the magnitude of the complex-valued

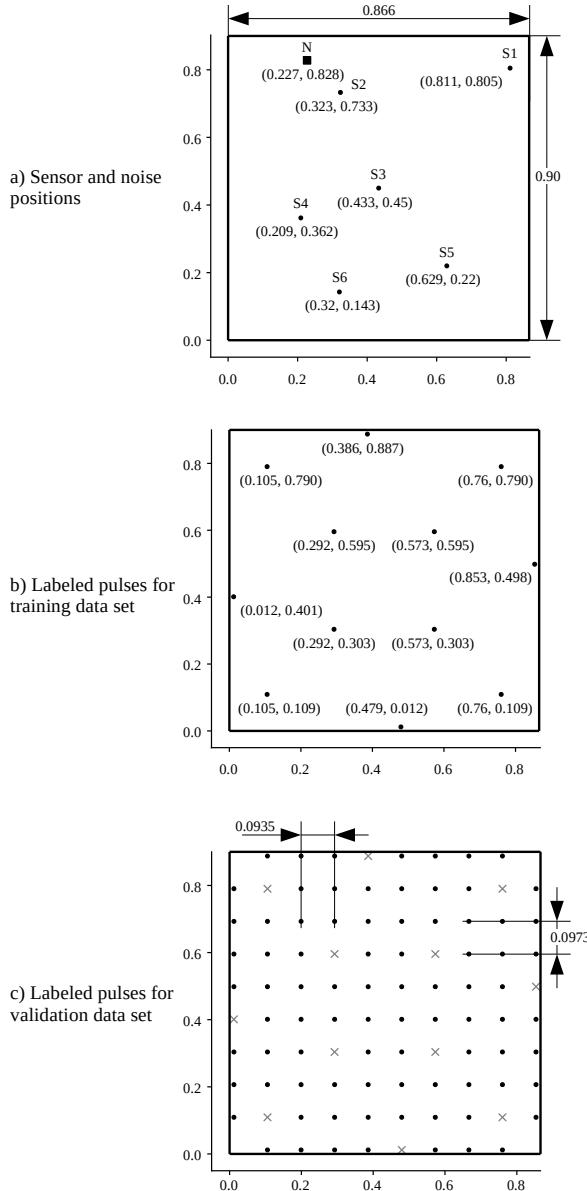

Figure 4.10.: Experimental setup for sensor analytics on structural health monitoring, all lengths are in meters (m).

STFT is employed in a spectrogram $\mathcal{S}_{m,k}$:

$$\mathcal{S}_{m,k} = \left| \mathcal{F}_{m,k}^{\gamma} \right|^2 = \left| \sum_{n=0}^{N-1} x[n] \cdot \gamma^*[n - m\Delta M] \cdot e^{\frac{-j2\pi kn}{N}} \right|^2 \quad (4.10)$$

In addition, these spectrograms are scaled in decibels. The spectrogram in decibels $\mathcal{S}_{m,k,\text{dB}}$

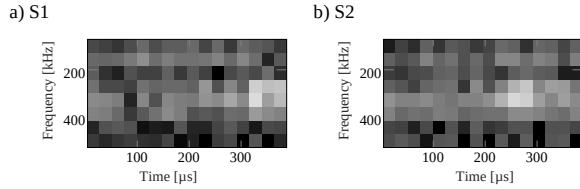

Figure 4.11.: Spectrograms of sensors S_1, S_2 converted to grayscale for pulses at $x = 0.105$ m, $y = 0.109$ m with noise disturbance.

produces $\mathcal{S}_{m,k,\text{dB}} = 20 \cdot \log_{10}(\mathcal{S}_{m,k})$. For conversion of data, the experiment uses a signal length of 400 μs (75 μs pretrigger and 325 μs post trigger). Thus, the arrival times of the pulses are included in the spectrogram for all channels and labeled positions. This uses Blackman window function [102], Fast Fourier Transform (FFT) length of 32 samples, and overlap of 8 samples. The spectrograms are calculated for frequencies in the range of 100 kHz to 500 kHz. This produces a spectrogram size of 8x16 (8 frequency bins, 16 time values).

In order to generate larger data sets, four further variants are created with time shifts of 15 μs / 30 μs / 45 μs / 60 μs . Subsequently, all spectrograms are converted to grayscale with scaling between -100 dB and -40 dB, see **Fig. 4.11**.

In overall, the data set has a size of 1,440,000 images. This is the result of 500 (pulses) \cdot 5 (spectrograms) \cdot 6 (listening sensors) \cdot 96 (excitation points).

CNN-Regression Model

The data analytics is implemented with a CNN-regression model, see **Fig. 4.12**. The structure of the model is described below:

- Input tensor. This is composed of spectrograms from the sensor signals. The tensor shape is defined by $S \times T \times F$, where S is the number of sensors, and $T \times F$ is the time-frequency resolution of the spectrograms, see **Fig. 4.12(a)**.
- Feature extraction. This is composed of three blocks of convolution, batch normalization, and max-pooling layers, see **Fig. 4.12(b)**. The number of channels in the convolution layers are defined by the hyper-parameters A , B , and C .
- Regression function. This is an arbitrary function implemented with two fully connected layers and an output layer with linear activation, see **Fig. 4.12(c)**.

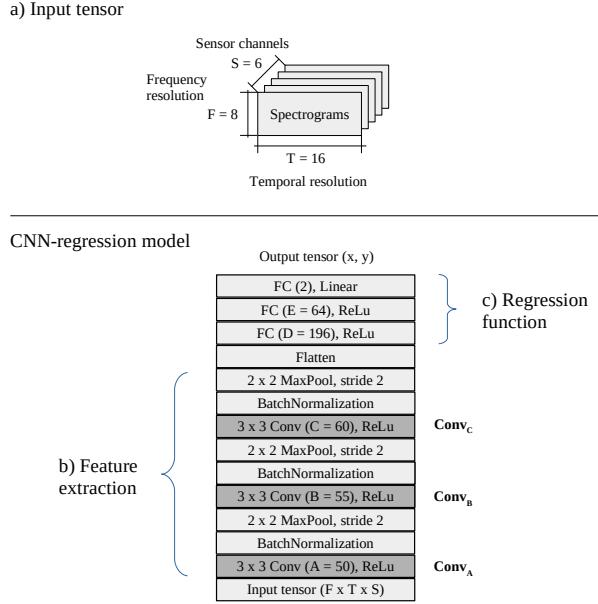

Figure 4.12.: CNN-regression model for sensor analytics.

4.4.2. Training

Base Model

The model in **Fig.** 4.12 is trained using Adam algorithm with iterative search. The Adam optimizer is configured with the default settings presented in [103]: $\alpha = 0.001$, $\beta_1 = 0.9$, $\beta_2 = 0.999$, and $\epsilon = 1e-8$. The training-cycle has a patience of 10 iterations before stop, the optimizer is executed with early stop patience of 10 epochs, and mini-batch size of 512 samples. This is applied using the method described in **Algorithm ??** with $N_I = 10$, $N_E = 10$, $B_{size} = 512$.

The training results are illustrated in **Fig.** 4.13(a). In this optimization, the initial and the final models achieve $MSE = 0.0135 \text{ m}^2$ and $MSE = 0.0122 \text{ m}^2$, respectively. The MSE is calculated with the Euclidean distance (loss) between the real/expected and the predicted/inferred coordinates. The initial model is obtained at the first early stop (after 10 epochs). In each stop, the moving averages of the Adam optimizer get re-initialized. This facilitates searching for better local minima. The model gets saved/updated when finding a better minimum.

The final model achieves $MSE = 0.0122 \text{ m}^2$, which corresponds to $MAE = 0.0955 \text{ m}$. See **Fig.** 4.14(a). In total, the training takes 379 epochs in 25 cycle-search iterations. The first search takes 43 epochs for the initial model and subsequent search iterations take an average of 14 epochs. The total time is 53 minutes using a Personal Computer (PC) with AMD Ryzen 5 5600H and NVIDIA GeForce RTX 3050 GPU.

4. Accelerating Convolutional Neural Networks

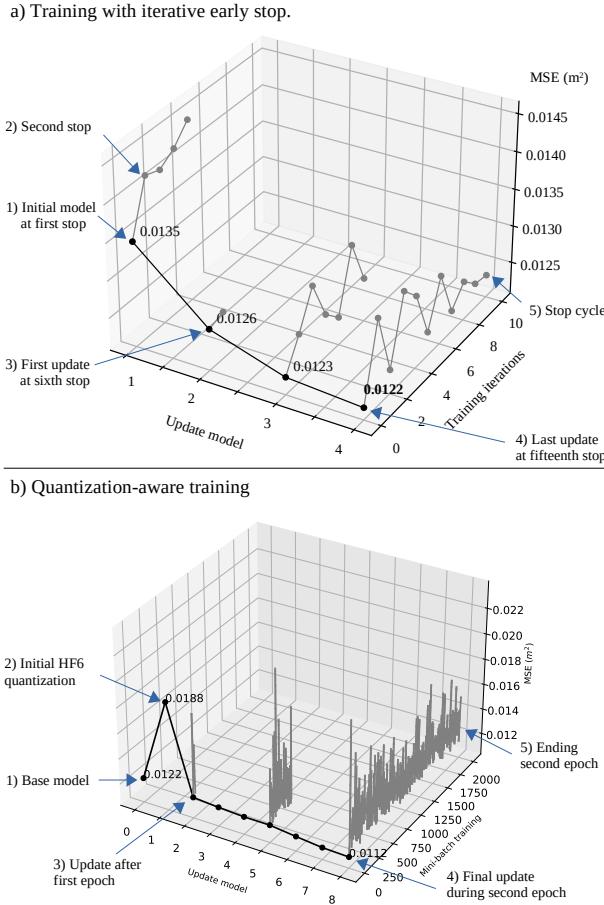

Figure 4.13.: Training results.

TensorFlow Lite 8-bit Quantization

This optimization method converts filter and bias tensors as well as activation maps to 8-bit integer representation, this allows inference using integer-only arithmetic [100]. In this research, this quantization is applied only to the convolution layers as they are the compute bound operations. Other layers employ 32-bit FP representation.

In the compute graph, the input and output feature maps are glued with linear quantization at the input and output of the *Conv2D* operations.

The base model is quantized using the TensorFlow Lite library with integer-only quantization on the *Conv2D* tensor operations. The filter and bias tensors are represented by 8-bit and 32-bit signed integers, respectively. The input and output activation maps are represented by 8-bit signed integer. The TensorFlow quantization includes two additional vectors (output-multiplier and output-shift coefficients), these two vectors are the same shape as the bias vector with 32-bit

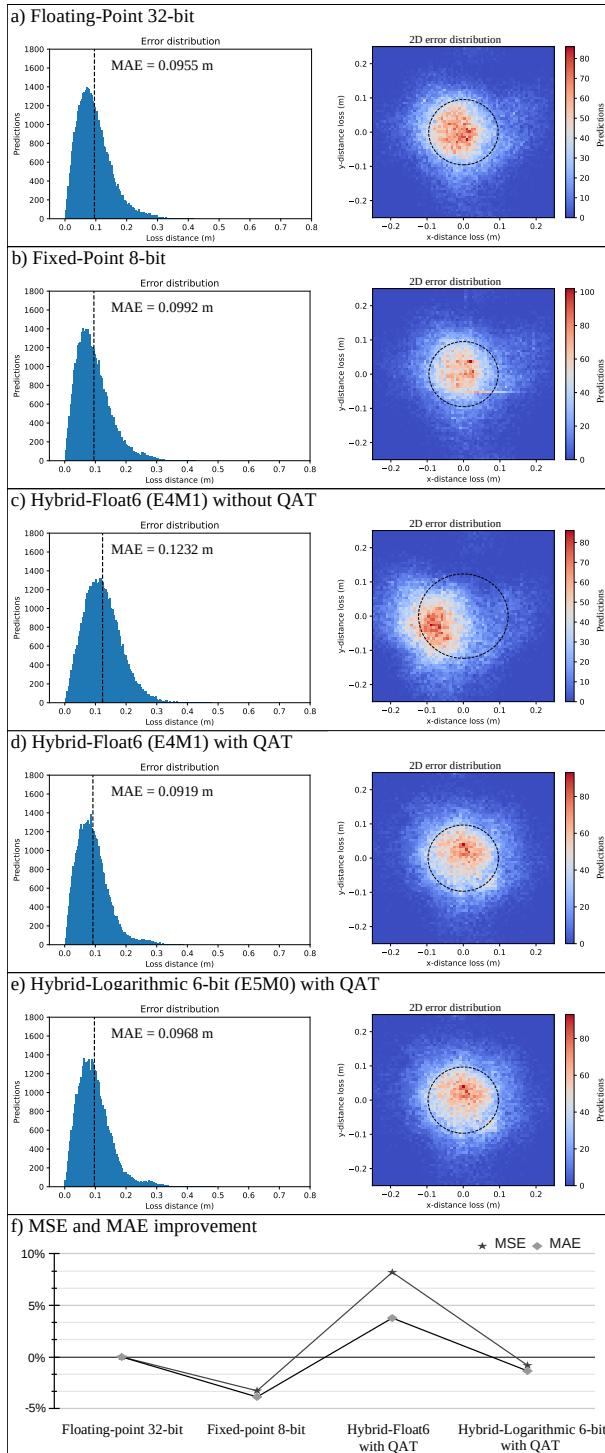

Figure 4.14.: Performance of the model with different data representations.

integer representation.

This model achieves $MSE = 0.0126 \text{ m}^2$ and $MAE = 0.0992 \text{ m}$. See Fig. 4.14(b). The MAE

increases 5.1% of the base model. We attribute this degradation to the 8-bit quantization on the *Conv2D* layers.

Inference of non-quantized models on HF6 hardware

To demonstrate backward compatibility, the inference quality of the base model is measured without quantization on the HF6 hardware. See **Fig. 4.14(c)**. This obtains $MSE = 0.0188 \text{ m}^2$ and $MAE = 0.1232 \text{ m}$. The MAE increases 29.5% of the base model. We attribute this degradation to the rounding errors of non-quantized filters and bias in *Conv2D* layers.

Quantization-Aware Training for HF6 hardware

The QAT is a post-training optimization. This has been run during two epochs with mini-batch size of 10 samples. This quantization is executed targeting the HF6 format: 4-bit exponent and 1-bit mantissa. This is applied to filter and bias tensors of *Conv2D* layers. This method is described in **Algorithm ??** with $N_{ep} = 2$, $B_{size} = 10$, $E_{size} = 4$, $M_{size} = 1$. The optimization results are illustrated in **Fig. 4.13(b)**.

The resulting model achieves $MSE = 0.0112 \text{ m}^2$ and $MAE = 0.0919 \text{ m}$. This corresponds to an error reduction of 8.2% and 3.77%, respectively. We attribute this improvement to the regularization effect. See **Fig. 4.14(d)**. The QAT time is 185 minutes.

Quantization-Aware Training for Hybrid-Logarithmic 6-bit

For the sake of quality comparison with logarithmic quantization, the model with 6-bit logarithmic representation is generated. See **Fig. 2.4(e)**. This quantization matches the bit size of HF6. The filter and bias tensors of *Conv2D* layers are quantized with the 6-bit logarithmic format: 1-bit sign, 5-bit signed exponent, and 0-bit mantissa. This is applied using the method described in **Algorithm ??** with $N_{ep} = 2$, $B_{size} = 10$, $E_{size} = 5$, $M_{size} = 0$.

The model achieves $MSE = 0.0123 \text{ m}^2$ and $MAE = 0.0968 \text{ m}$, which correspond to an error increase of 0.82% and 1.36%, respectively. We attribute this degradation to the 6-bit logarithmic quantization lacking fractional bits. See **Fig. 4.14(e)**.

A summary of improvement-degradation of MSE and MAE with different data representations is presented in **Fig. 4.14(f)**.

4.4.3. Hardware Design Exploration

The proposed hardware/software co-design is demonstrated on the Zynq-7007S SoC on the MiniZed development board. This SoC integrates a single ARM Cortex-A9 PS and a PL equivalent

to Xilinx Artix-7 FPGA in a single chip [84]. The Zynq-7007S SoC architecture maps the custom logic and software in the PL and PS, respectively.

In this platform, the proposed hardware/software architecture is implemented to deploy the sensor analytics application. The desired model is converted to TensorFlow Lite (floating-point) and deployed on the embedded software as a hex dump as a C array. The Zynq-7007S SoC executes inference with TensorFlow Lite on the PS. The computational workload of convolution layers is delegated to the dedicated hardware.

Benchmark on Embedded CPU

First, the performance of the embedded CPU is explored for inference without hardware acceleration. In this case, TensorFlow Lite creates the CNN model as a sequential compute graph executing all computation on the CPU (ARM Cortex-A9) at 666 MHz with power dissipation of 1,187 W.

The compute performance and run-time inference of the CPU are shown in **Tab. 4.2(a)** and **Fig. 4.16(a)**, respectively.

Benchmark on Tensor Processor Synthesized with Xilinx LogiCORE IP for Floating-Point Computation

For this design, the TP is implemented with standard Xilinx FP hardware prior synthesis. The design parameters for the maximum required accelerator on-chip size are:

- Max convolution kernel size: $K_W = K_H = 3$.
- Max input tensor width: $W_I = 16$.
- Max input and output channels: $C_I = 55, C_O = 60$.
- Filter and bias bit size: $BitSize_F = BitSize_B = 32$.
- Input tensor bit size: $BitSize_I = 32$.

Using equations from Section 4.3.2, the on-chip memory utilization are $Input_M = 84,480\text{b}$, $Filter_M = 950,400\text{b}$, and $Bias_M = 1,920\text{b}$. Hence, the required on-chip memory buffer size is $TP_B = 1,036,800\text{b}$.

The post-implementation resource utilization and power dissipation are presented in **Tab. 4.1(a)**. The complete hardware platform utilizes 83% of BRAM, this includes the on-chip memory requirements of the TP, DMA, and AXI interconnects. The total available on-chip memory (BRAM)

4. Accelerating Convolutional Neural Networks

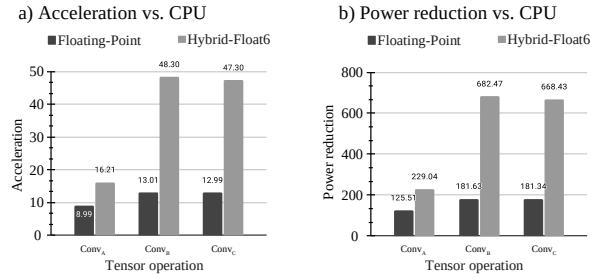

Figure 4.15.: Inference acceleration and power reduction on the TP with floating-point and HF6 vs. CPU on the Zynq-7007S SoC.

on the Zynq-7007S SoC is 1.8 Mb. After hardware syntheses, the estimated power dissipation of the TP is 85 mW at 200 MHz (this estimation is provided by Xilinx Vivado).

Table 4.1.: Resource utilization and power dissipation on the Zynq-7007S SoC.

TP engine	Post-implementation resource utilization				Power (W)
	LUT	FF	DSP	BRAM 36Kb	
(a) Floating-Point	5,578 39%	8,942 31%	23 35%	41.5 83%	1.429
(b) Hybrid-Float6	7,313 51%	10,330 36%	20 30%	15 30%	1.424

The compute performance and inference schedule of the model on this hardware implementation are shown in **Tab. 4.2(b)** and **Fig. 4.16(b)**, respectively. During run-time, the software (TensorFlow Lite) delegates computation to the TP as dedicated hardware for *Conv2D* tensor operations.

The implementation of the dot-product with standard FP engine (IEEE 754 arithmetic) utilizes proprietary multiplier and adder floating-point operator cores. Vivado HLS implements FP arithmetic operations by mapping them onto Xilinx LogiCORE IP cores, these FP operator cores are instantiated in the resultant RTL [85]. In this case, the implementation of the dot-product with the standard FP computation reuses the multiplier and adder cores in different compute sections of the TP. The post-implementation resource utilization and power dissipation of the individual floating-point operator cores are shown in **Tab. 4.3**.

Tensor Processor Synthesized with Hybrid-Float6 Hardware Architecture

To demonstrate the proposed design, the TP with HF6 hardware reuses the standard FP design parameters with the following variation for the 6-bit representation in filter and bias: $BitSize_F = BitSize_B = 6$.

Table 4.2.: Compute performance of the CPU and TP on each Conv2D tensor operation. This table presents: tensor operation, computational cost in mega floating-point operations (MFLOP), latency, throughput, power efficiency, and estimated energy consumption as the energy delay product (EDP).

Operation	MFLOP	t (ms)	MFLOP/s	MFLOP/s/W	EDP (mJ)
a) CPU (ARM Cortex-A9) @666MHz, 1.187 W					
Conv_A	0.691	112.24	6.16	5.19	133.23
Conv_B	1.584	213.13	7.43	6.26	252.99
Conv_C	0.475	46.59	10.20	8.59	55.31
b) TP (Floating-Point engine) @200MHz, 85 mW					
Conv_A	0.691	12.49	55.34	651.11	1.06
Conv_B	1.584	16.39	96.66	1,137.20	1.39
Conv_C	0.475	3.59	132.44	1,558.13	0.30
c) TP (Hybrid-Float6 engine) @200MHz, 84 mW					
Conv_A	0.691	6.92	99.81	1,188.24	0.58
Conv_B	1.584	4.41	358.94	4,273.09	0.37
Conv_C	0.475	0.99	482.44	5,743.29	0.08

Table 4.3.: Resource utilization and power dissipation of individual multiplier and adder floating-point (IEEE 754) operator cores (Xilinx LogiCORE IP).

Core operation	DSP	FF	LUT	Latency (clk)	Power (mW)
Multiplier	3	151	325	4	7
Adder	2	324	424	8	6

Using equations from Section 4.3.2, the on-chip memory requirements for the hardware accelerator are $Input_M = 84,480 \text{ b}$, $Filter_M = 178,200 \text{ b}$, $Bias_M = 360 \text{ b}$. Hence, the required on-chip memory buffer size is $TP_B = 263,040 \text{ b}$.

The post-implementation resource utilization and power dissipation are presented in **Tab. 4.1(b)**. The complete hardware platform utilizes 30% of BRAM, this includes the on-chip memory requirements of the TP, DMA, and AXI interconnects. The estimated power dissipation of the TP is 84 mW at 200 MHz (this estimation is provided by Xilinx Vivado).

The compute performance and inference schedule of the model on this hardware implementation are shown in **Tab. 4.2(c)** and **Fig. 4.16(c)**, respectively. **Fig. 4.15** presents a comparison of the acceleration and the reduction of power dissipation between standard FP and HF6 hardware implementations.

This deployment does not require model treatment for hardware compatibility. For backward compatibility, the 6-bit FP representation is wrapped into the standard FP. The dedicated hardware design extracts the 6-bit format automatically to perform computation.

4. Accelerating Convolutional Neural Networks

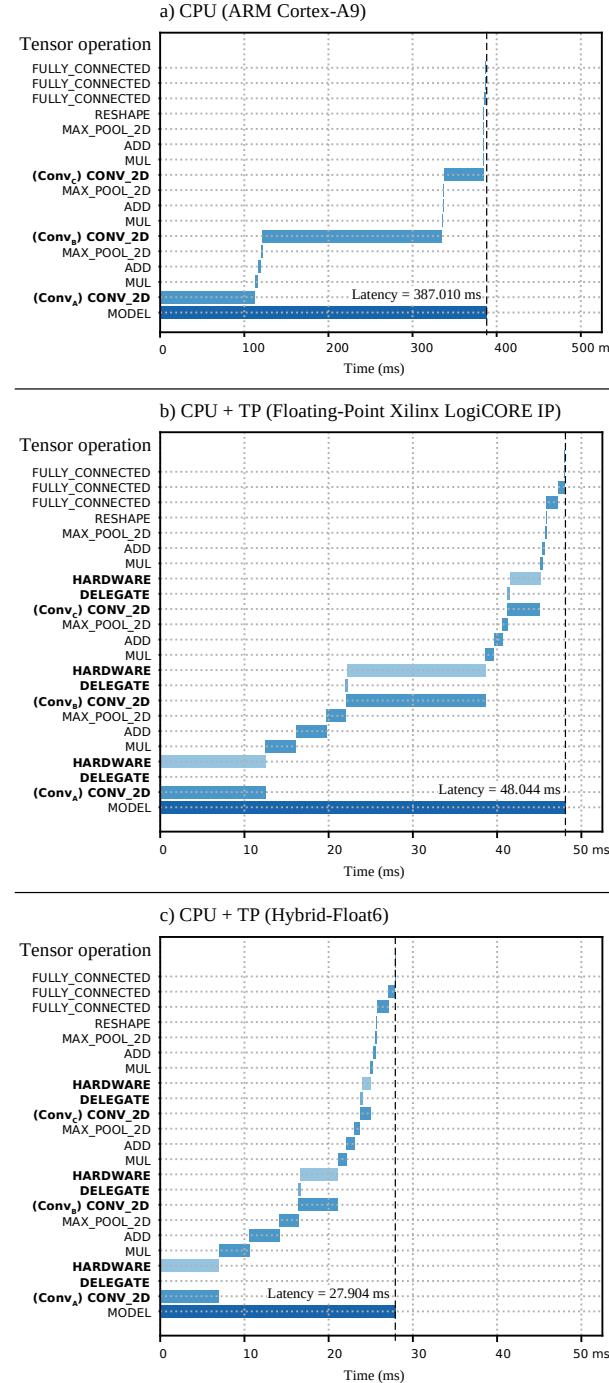

Figure 4.16.: Run-time inference of TensorFlow Lite on the Zynq-7007S SoC. (a) CPU ARM Cortex-A9 at 666 MHz, (b) cooperative CPU + TP with floating-point Xilinx LogiCORE IP at 200 MHz, and (c) cooperative CPU + TP with Hybrid-Float6 at 200 MHz.

4.4.4. Discussion

Training and Quantization

The training with iterative early stop obtains a model with enhanced accuracy than standard early stop. This method iteratively resets the moving averages of Adam’s optimizer, which helps to iteratively search for better local minima. This iterative search is suitable for models with low computational cost.

The TensorFlow Lite 8-bit quantization preserves the overall model accuracy. In some cases, the associated regularization effect can improve the accuracy. However, the error distribution in CNN linear regressions gets slightly degraded. In particular, 8-bit quantized output layers incur in discrete-degradation patterns, **Fig. 4.17(b)** shows this effect on three different models. Vertical and horizontal patterns appear in the error distribution of 8-bit fixed-point quantization. We attribute this effect to the 8-bit resolution in the activation maps. In the case of HF6 quantization, the activation maps are represented by floating-point preventing this degradation.

The proposed 6-bit FP representation (E4M1) improves latency, hardware area, and power dissipation, while preserving model accuracy. For comparison, in our application, this number format produces better results than the 6-bit logarithmic representation (E5M0). This is demonstrated in **Fig. 4.14(d)** and **Fig. 4.14(e)**.

In [96], Lai et al. demonstrated that 4-bit exponent and X-bit mantissa preserves accuracy on SqueezeNet, AlexNet, GoogLeNet, and VGG-16. To contribute on this, we investigate 4-bit exponent and 1-bit mantissa to ALL-CNN-C [104], this produces an accuracy degradation of 1.39% and 0.11% with QAT. While applying 6-bit logarithmic produces a degradation of 11.18% and 7.22% with QAT.

Implementation and Performance

The proposed HF6 implementation reduces on-chip memory and DSP utilization while slightly increasing FF and LUT compared to the standard FP implementation. See **Tab. 4.1** and **Fig. 4.18**. We attribute this to the HF6 logic implementation using FF and LUT, while the FP logic implementation uses Xilinx LogiCORE IPs mainly with DSPs.

The compute performance of the CPU and TP on each convolution layer is presented in **Tab. 4.2** and **Fig. 4.15**. The peak acceleration and power efficiency of the TP with standard FP (Xilinx LogiCORE IP) is 13 \times and 1,558.13 MFLOPS/s/W, respectively. While the peak acceleration and power efficiency of the TP with HF6 is 48.3 \times and 5,743.29 MFLOPS/s/W, respectively. The HF6 hardware demonstrates an improvement of 3.7 \times in acceleration and power efficiency with respect to the standard FP hardware. See **Fig. 4.15**.

4. Accelerating Convolutional Neural Networks

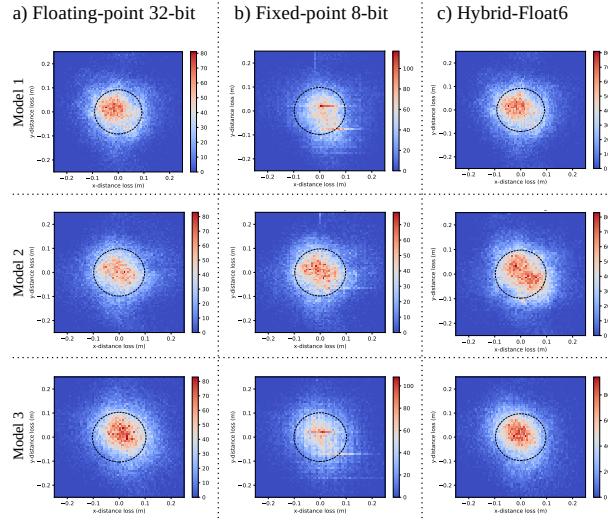

Figure 4.17.: 2D error distribution of three CNN-regression models.

The estimated power dissipation on the SoC is presented in **Fig. 4.19**. This shows a very similar breakdown of power dissipation in both implementations. However, the energy efficiency is increased due to the reduced latency in HF6 hardware. A comparison of related work is presented in **Tab. 4.4**.

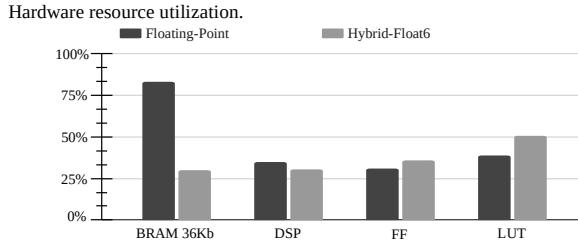

Figure 4.18.: Hardware resource utilization on the Zynq-7007S SoC.

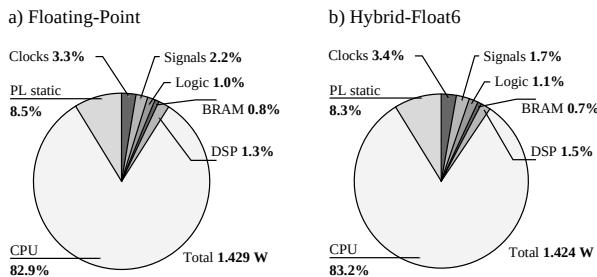

Figure 4.19.: Estimated power dissipation on the Zynq-7007S SoC with PS at 666 MHz and PL at 200 MHz.

The run-time inference of TensorFlow Lite on the SoC is illustrated in **Fig. 4.16**. This shows

the convolution layers as the compute-bound operations. The proposed embedded platform is a cooperative system where the convolution operations are delegated to the dedicated hardware accelerator. The ARM CPU obtains a latency of 387 ms (2.58 FPS). The platform with standard FP hardware obtains a latency of 48 ms (20.8 FPS), while the implementation with HF6 obtains a latency of 27.9 ms (35.84 FPS). These represent an overall acceleration of 8 \times and 13.87 \times over the CPU, respectively.

This design facilitates ML compatibility/portability as the 6-bit FP is wrapped in the standard FP representation. The dedicated hardware design extracts the 6-bit format automatically and performs computation.

SoC Design and Compatibility

The proposed design is an alternative for high accuracy and low-power floating-point inference. The system runs as a cooperative hardware/software mechanism. This architecture delegates compute-bound tensor operations to a hardware accelerator.

The hybrid 32-bit FP and 6-bit FP quantization enables high quality of results and backward ML compatibility. Backwards ML compatibility gives portability from training to inference. This enables to run inference of HF6 quantized models on standard FP hardware and vice versa. The proposed HF6 architecture allows to compute inference of non-quantized floating-point ML models for rapid deployment; however, this will incur in accuracy degradation depending on the resilience of the model, see **Fig. 4.14(c)**.

Limitations and Directions for Future Work

In this research, we foresee three lines of future work:

- **To reduce energy consumption.** The proposed architecture consists of a hybrid floating-point quantization using 32-bit activation maps. These can be represented using lower-bit formats; for example, Bfloat16 and 8-bit or lower custom floating-point. This would reduce hardware resource utilization, memory footprint and data transfer, while preserving backward compatibility and accuracy (based on the dynamic value range of custom floating-point formats).
- **To increase performance.** This implementation requires matching higher computational throughput with memory bandwidth. This would replace the light-weight pipeline hardware design with a parallelized structure. This will increase hardware area and energy consumption. This can be achieved by using wider memory channels and systolic arrays to increase throughput.

Table 4.4.: Comparison of hardware implementation with related work.

Platform	Chunsheng Mei et al. [94]	Chen Wu et al. [92]	BFP [95]	Paolo Meloni et al. [98]	This work
Device	XC7VX690T	XC7K325T	XC7VX690T	XC7Z007S	XC7Z007S
Year	2017	2019	2019	2019	2022
Dev. kit cost	\$7,494	\$1,299	\$7,494	\$89	\$89
Format (activation/weight)	FP 16-bit	FP 8-bit / 8-bit	FP 16-bit / 8-bit	INT 16-bit	FP 32-bit / 6-bit
Frequency (MHz)	200	200	200	80	200
Peak power efficiency (GFLOP/s/W)	18.72	115.40	82.88	2.98	5.74

- **To use in computer vision applications.** This implementation is designed for sensor analytics workloads. For computer vision applications, the hardware design would require increased on-chip memory capacity for larger bias and filter vectors (using equations from Section 4.3.2), and higher computational throughput in a larger FPGA SoC.

4.5. Conclusions

In this paper, we present the Hybrid-Float6 quantization for floating-point CNN hardware acceleration. Feature maps and weights are represented by 32-bit and 6-bit floating-point, respectively. The 6-bit floating-point format is composed of 1-bit sign, 4-bit exponent, and 1-bit mantissa. The 1-bit mantissa enables low-power multiply-accumulate implementations by reducing the mantissa multiplication to a multiplexer-adder operation. We exploit the intrinsic error tolerance of neural networks to further reduce the hardware design with approximation. This approach improves latency, hardware area, and energy consumption. To preserve accuracy, we introduce a quantization-aware training method that, in some cases, improves accuracy. We present a lightweight tensor processor implementing a pipelined vector dot-product. For ML compatibility/portability, the 6-bit FP is wrapped in the standard floating-point format, which is automatically extracted by the proposed hardware. The hardware/software architecture is compatible with TensorFlow Lite. We evaluate the applicability of our approach with a CNN-regression model for anomaly localization in a structural health monitoring application based on acoustic emissions. The embedded hardware/software framework is demonstrated on XC7Z007S as the smallest Zynq-7000 SoC. The proposed architecture achieves a peak power efficiency and acceleration on convolution layers of 5.7 GFLOPS/s/W and 48.3×, respectively.

5. Conclusion and Outlook

5.1. Summary of Contributions	78
5.2. Future Works	78

The use of AI is entering a new era based on the use of ubiquitous embedded connected devices. The sustainability of this transformation requires the adoption of design techniques that reconcile accurate results with cost-effective system architectures. As such, improving the efficiency of AI hardware engines as well as ML portability must be considered.

In the emerging era of Industry 4.0, ML algorithms yield the power of AI to massively ubiquitous IoT devices. Applications in this field become smarter and more profitable as the availability of big data gets expanded, driving evolution of many aspects in science, industry, and daily life. However, state-of-the-art ML algorithms, specially SNN and CNN, represent elevated computational and energy costs. Therefore, hardware efficiency is one of the major goals to innovate compute engines as they are the machinery of the future.

Energy, performance, and chip-area are the key design concerns in computer systems. Considering the intrinsic error resilience of ML algorithms, paradigms such as approximate computing come to the rescue by offering promising efficiency gains to assist the aforementioned design concerns. Approximation techniques are widely used in ML algorithms at the model-structure as well as at the hardware processing level. However, state-of-the-art methods do not sufficiently address accelerator designs for ANN, in particular with FP computation.

To sustain the continuous expansion of ML applications on cost-effective compute devices, approximate computing will gradually transform from a design alternative to an essential prerequisite. This dissertation focuses on the investigation of design methodologies to exploit the intrinsic error resilience of ML algorithms to optimize FP inference in low-power embedded systems.

5.1. Summary of Contributions

In the field of SNN, this dissertation presents a hardware design methodology for low-power inference of SbS neural networks targeting embedded applications. This ML algorithm provides exceptional noise robustness and reduced complexity compared to conventional SNN with LIF mechanism. However, SbS networks represent a memory footprint and a computational cost unsuitable for embedded applications. To address this problem, this work exploits the intrinsic error resilience of SbS to improve performance and to reduce hardware complexity. More precisely, we design a vector dot-product module based on approximate computing with configurable quality using hybrid custom FP and logarithmic number representations. This approach reduces computational run-time, memory footprint, and power dissipation while preserving inference accuracy. To demonstrate this approach, we address a design exploration flow with HLS on a FPGA. The proposed design reduces $20.5\times$ run-time and $8\times$ weight memory footprint, with less than 0.5% of accuracy degradation without retraining on a handwritten digit classification task.

In the field of CNN, this dissertation presents a hardware design methodology for low-power inference targeting sensor analytics applications. In this work, we present the HF6 quantization and its dedicated hardware processor. We propose an optimized FP MAC hardware by reducing the mantissa multiplication to a multiplexer-adder operation. We exploit the intrinsic error tolerance of neural networks to further reduce the hardware design with approximation on the subnormal number computation. To preserve model accuracy, we present a QAT method, which in some cases improves accuracy. We demonstrate this concept in 2D convolution layers. We present a lightweight TP implementing a pipelined vector dot-product. For ML portability, the custom FP representation is wrapped in the standard format, which is automatically extracted by the proposed hardware. The hardware/software architecture is integrated with TF Lite. We evaluate the applicability of our approach with a CNN-regression model for anomaly localization in a SHM application based on AE. The embedded hardware/software framework is demonstrated on XC7Z007S as the smallest Zynq-7000 SoC. The proposed implementation achieves a peak power efficiency and acceleration of 5.7 GFLOPS/s/W and $48.3\times$, respectively.

The outcome of this dissertation aims to contribute to the rise of a sustainable next generation of low-power FP neural network processors with ML portability as a design philosophy.

5.2. Future Works

A. Appendix

A.1. SbS algorithm

The SbS network inference is described in **Algorithm 5**, while spike production and layer update are described in **Algorithm 6** and **Algorithm 7**, respectably.

Algorithm 5: SbS network inference.

input: Layers of the network as H^l , where
 l is the layer index.
input: N_L as the number of layers.
input: N_X^l, N_Y^l as the size of layers.
input: N_{Spk} as the number of spikes for inference (iterations).
output: H^l .

for $t = 0$ **to** $N_{Spk} - 1$ **do**

Initialization of $H^l(i_X, i_Y, :)$:

if $t == 0$ **then**

for $l = 0$ **to** $N_L - 1$ **do**

for $i_X = 0, i_Y = 0$ **to** $N_X^l - 1, N_Y^l - 1$ **do**

for $i_H = 0$ **to** $N_H^l - 1$ **do**

Algorithm 6: Spike production.

input: Layer as $H_t \in \mathbb{R}^{N_X \times N_Y \times N_H}$, where
 N_X is the layer width,
 N_Y is the layer height
 N_H is the length of \vec{h} (IP vector).
output: Output spikes as $S_t^{out} \in \mathbb{N}^{N_X \times N_Y}$

```

1: for  $i_X = 0, i_Y = 0$  to  $N_X - 1, N_Y - 1$  do
2:   Generate spike :
3:    $th = MT19937PseudoRandom() / (2^{32} - 1)$ 
4:    $acu = 0$ 
5:   for  $i_H = 0$  to  $N_H - 1$  do
6:      $acu = acu + H_t(i_X, i_Y, i_H)$ 
7:     if  $th \leq acu$  or  $i_H == N_H - 1$  then
8:        $S_t^{out}(i_X, i_Y) = i_H$ 
9:     end if
10:   end for
11: end for

```

A. Appendix

Algorithm 7: SbS layer update.

input: Layer as $H \in \mathbb{R}^{N_X \times N_Y \times N_H}$, where

N_X is the layer width,

N_Y is the layer height

N_H is the length of \vec{h} (IP vector).

input: Synaptic matrix as $W \in \mathbb{R}^{K_X \times K_Y \times M_H \times N_H}$, where

$K_X \times K_Y$ is the size of the convolution/pooling kernel,

M_H is the length of \vec{h} from previous layer,

N_H is the length of \vec{h} from this layer.

input: Input spike matrix from previous layer as $S_t^{in} \in \mathbb{N}^{N_{Xin} \times N_{Yin}}$, where

N_{Xin} is the width of the previous layer,

N_{Yin} is the height of the previous layer.

input: Strides of X and Y as $stride_X$ and $stride_Y$, respectively.

input: Epsilon as $\epsilon \in \mathbb{R}$.

output: Updated layer as $H^{new} \in \mathbb{R}^{N_X \times N_Y \times N_H}$.

Update layer :

```

1:  $z_X = 0 //$  X and Y index for  $S_t^{in}$ 
2:  $z_Y = 0$ 
3: for  $i_Y = 0$  to  $N_Y - 1$  do
4:   for  $i_X = 0$  to  $N_X - 1$  do
5:      $\vec{h} = H(i_X, i_Y, :)$ 
      Update IP :
6:     for  $j_X = 0, j_Y = 0$  to  $K_X - 1, K_Y - 1$  do
7:        $s_t = S_t^{in}(z_X + j_X, z_Y + j_Y)$ 
8:        $\vec{w} = W(j_X, j_Y, s_t, :)$ 
9:        $\vec{p} = 0$ 
        Dot-product :
10:       $r = 0$ 
11:      for  $j_H = 0$  to  $N_H - 1$  do
12:         $\vec{p}(j_H) = \vec{h}(j_H)\vec{w}(j_H)$ 
13:         $r = r + \vec{p}(j_H)$ 
14:      end for
15:      if  $r \neq 0$  then
16:        Update IP vector :
17:        for  $i_H = 0$  to  $N_H - 1$  do
18:           $h^{new}(i_H) = \frac{1}{1+\epsilon} \left( h(i_H) + \epsilon \frac{\vec{p}(i_H)}{r} \right)$ 
19:        end for
        Set the new H vector for the layer :
20:         $H^{new}(i_X, i_Y, :) = \vec{h}^{new}$ 
21:      end if
22:    end for
23:     $z_X = z_X + stride_X$ 
24:  end for
25:   $z_Y = z_Y + stride_Y$ 
26: end for

```

Acronyms

List of Figures

2.1.	SbS network architecture for handwritten digit classification task.	13
2.2.	SbS IPs as independent computational entities, (a) illustrates an input layer with a massive amount of IPs operating as independent computational entities, (b) shows a hidden layer with an arbitrary amount of IPs as independent computational entities, (c) exhibits a set of neurons grouped in an IP.	13
2.3.	(a) Performance classification of SbS NN versus equivalent CNN, and (b) example of the first pattern in the MNIST test data set with different amounts of positive additive uniformly distributed noise.	14
2.4.	Floating-point number representation.	16
3.1.	Dot-product hardware module with (a) standard floating-point (IEEE 754) arithmetic, (b) hybrid custom floating-point approximation, and (c) hybrid logarithmic approximation.	20
3.2.	System-level overview of the embedded software architecture.	23
3.3.	System-level hardware architecture with scalable number of heterogeneous PUs: <i>Spike</i> , <i>Conv</i> , <i>Pool</i> , and <i>FC</i>	24
3.4.	The <i>Conv</i> processing unit and its six stages: (a) receive IP vector, (b) spike firing, (c) receive spike kernel, (d) update dynamics, (e) dispatch new IP vector, (f) dispatch output spike matrix.	26
3.5.	Dot-product hardware module with standard floating-point (IEEE 754) computation, (a) exhibits the initiation interval of 10 clock cycles, (b) presents the iteration latency of 19 clock cycles, (c) shows the pairwise product block in dark-gray, and (d) illustrates the accumulation block in light-gray.	28
3.6.	Dot-product hardware module with hybrid custom floating-point approximation, (a) exhibits the initiation interval of 2 clock cycles, (b) presents the iteration latency of 13 clock cycles, (c) shows the pairwise product blocks in dark-gray, and (d) illustrates the accumulation blocks in light-gray.	29

3.7. Dot-product hardware module with hybrid logarithmic approximation, (a) exhibits the initiation interval of 2 clock cycles, (b) presents the iteration latency of 9 clock cycles, (c) shows the pairwise product block in dark-gray, and (d) illustrates the accumulation blocks in light-gray.	30
3.8. Computation on embedded CPU.	33
3.9. System overview of the top-level architecture with 8 processing units.	33
3.10. Performance of processing units with standard floating-point (IEEE 754) computation.	33
3.11. Performance bottleneck of cyclic computation on processing units with standard floating-point (IEEE 754) arithmetic, (a) exhibits the starting of t_{PU} of <i>Conv2</i> on a previous computation cycle, (b) presents t_{CPU} of <i>Conv2</i> on the current computation cycle, (c) shows the CPU waiting time (in gray color) for <i>Conv2</i> as a busy resource (awaiting for <i>Conv2</i> interruption), and (d) illustrates the t_f from the previous computation cycle, the starting of t_{PU} on the current computation cycle (<i>Conv2</i> interruption on completion, and start current computation cycle).	34
3.12. Noise tolerance on hardware PU with standard floating-point (IEEE 754) computation (benchmark/reference), (a) exhibits accuracy degradation applying 50% of noise amplitude, and (b) illustrates convergence of inference with 400 spikes.	37
3.13. \log_2 -histogram of each synaptic weight matrix showing the percentage of matrix elements with given integer exponent.	39
3.14. Performance on processing units with hybrid custom floating-point approximation, (a) exhibits computation schedule, (b) presents cyclic computation schedule, and (c) shows the performance of <i>Conv2</i> from a previous computation cycle during the preprocessing of <i>H1_CONV</i> on the current computation cycle without bottleneck.	40
3.15. Noise tolerance on hardware PU with custom floating-point approximation, (a) exhibits accuracy degradation applying 50% of noise amplitude, and (b) illustrates convergence of inference with 400 spikes.	41
3.16. Performance of processing units with hybrid logarithmic approximation, (a) exhibits computation schedule, and (b) illustrates cyclic computation schedule.	42
3.17. Noise tolerance on hardware PU with hybrid logarithmic approximation, (a) exhibits accuracy degradation applying 40% of noise amplitude, (b) illustrates convergence of inference with 600 spikes.	43

3.18. Power dissipation breakdown of platform implementations, (a) ?? architecture with homogeneous AUs using standard floating-point arithmetic (IEEE 754), (b) reference architecture with specialized heterogeneous PUs using standard floating-point arithmetic (IEEE 754), (c) proposed architecture with hybrid custom floating-point approximation, and (d) proposed architecture with hybrid logarithmic approximation.	45
4.1. The workflow of our approach on embedded FPGAs.	49
4.2. Base embedded system architecture.	52
4.3. High level hardware architecture of the proposed tensor processor.	52
4.4. Dot-product hardware module with (a) standard floating-point and (b) Hybrid-Float6.	54
4.5. (a) Dot-product hardware module with Hybrid-Float6 MAC, (b) bias accumulation, (c) activation and normalization to IEEE754.	54
4.6. Hybrid-Float6 multiply-accumulate hardware design.	55
4.7. Design parameters for on-chip memory buffers on the TP.	56
4.8. High level embedded software architecture.	59
4.9. Software flowchart.	59
4.10. Experimental setup for sensor analytics on structural health monitoring, all lengths are in meters (m).	63
4.11. Spectrograms of sensors S_1, S_2 converted to grayscale for pulses at $x = 0.105$ m, $y = 0.109$ m with noise disturbance.	64
4.12. CNN-regression model for sensor analytics.	65
4.13. Training results.	66
4.14. Performance of the model with different data representations.	67
4.15. Inference acceleration and power reduction on the TP with floating-point and HF6 vs. CPU on the Zynq-7007S SoC.	70
4.16. Run-time inference of TensorFlow Lite on the Zynq-7007S SoC. (a) CPU ARM Cortex-A9 at 666 MHz, (b) cooperative CPU + TP with floating-point Xilinx LogiCORE IP at 200 MHz, and (c) cooperative CPU + TP with Hybrid-Float6 at 200 MHz.	72
4.17. 2D error distribution of three CNN-regression models.	74
4.18. Hardware resource utilization on the Zynq-7007S SoC.	74
4.19. Estimated power dissipation on the Zynq-7007S SoC with PS at 666 MHz and PL at 200 MHz.	74

List of Tables

2.1.	SbS network architecture for handwritten digit classification task.	14
3.1.	Computation on embedded CPU.	32
3.2.	Performance of processing units with standard floating-point (IEEE 754) computation.	34
3.3.	Resource utilization and power dissipation of processing units with standard floating-point (IEEE 754) computation.	36
3.4.	Resource utilization and power dissipation of multiplier and adder floating-point (IEEE 754) operator cores.	36
3.5.	Resource utilization and power dissipation of processing units with hybrid custom floating-point approximation.	39
3.6.	Performance of hardware processing units with hybrid custom floating-point approximation.	40
3.7.	Performance of hardware processing units with hybrid logarithmic approximation.	42
3.8.	Resource utilization and power dissipation of processing units with hybrid logarithmic approximation.	42
